Defying the paradigm — rescue thrombolysis in a postoperative patient with pulmonary embolism

Parenteral anticoagulation is recommended for patients of pulmonary embolism with intermediate to high early mortality risk. Rescue reperfusion is considered if signs of hemodynamic decompensation appear. Recent surgery within last 3 weeks is considered to be an absolute contraindication to thrombolytic therapy [1]. Percutaneous catheter-directed thrombolysis and surgical embolectomy can be done in such patients. However, they are not readily available. We hereby report a case of rescue thrombolysis in a post lower segment caesarean section (LSCS) patient with pulmonary thromboembolism. We successfully achieved thrombolysis in our patient with improvement in clinical and hemodynamic parameters and with no major bleeding from any site.

A 21-year-old married female was admitted to the intensive care unit with complaints of sudden shortness of breath and dizziness since last 6 hours. She had 2 episodes of syncope followed by spontaneous regaining of consciousness within 10 minutes. The patient had undergone LSCS 2 weeks back and had reduced mobility since then. On admission, she had tachypnea, tachycardia, was normotensive and hypoxic on room air. There were no signs of deep venous thrombosis. Arterial blood gases on ambient air revealed respiratory alkalosis with hypoxemia. Chest radiograph did not disclose any significant abnormality. Electrocardiogram showed right axis deviation and RV strain pattern. Her Wells and Revised Geneva scores were suggestive of intermediate risk of pulmonary embolism and as D-dimer was raised, urgent CT pulmonary angiography was performed which revealed a thrombus in both right and left pulmonary arteries and infarction involving the right middle lobe and posterior basal segment of the left lower lobe (Figure 1). 2D- Echo-cardiogram revealed dilatation of the right atrium and ventricle, positive McConnels sign with raised pulmonary artery systolic pressure of 60 mm Hg. NT-ProBNP was elevated (4054 pg/mL). Compression venous ultrasonography of bilateral lower limbs showed deep vein thrombosis of the right saphenous-femoral vein and popliteal vein. Her simplified pulmonary embolism severity index (sPESI) was 2. As she had intermediate high early mortality risk, she was started on initial parenteral anticoagulation with unfractionated heparin. However, after few hours, she developed hypotension which was nonresponsive.

Figure 1. A. CTPA image showing a thrombus in both right and left pulmonary arteries; B. Lung window showing wedge-shaped infarct in the left lower lobe
to crystalloid bolus infusion and sPESI deteriorated to 3. Repeated 2D-echo revealed bowing of the inter-ventricular septum to the left in addition to previous findings.

Recent surgery within 3 weeks is considered as an absolute contraindication to systemic thrombolysis. A retrospective study and several case reports of patients with pulmonary embolism with various contraindications have shown that successful thrombolysis is possible in these patients [2–5] (Table 1).

In view of high mortality risk, and as catheter-directed thrombolysis was not immediately available, a decision to initiate rescue thrombolysis with streptokinase was taken. Risks and benefits of thrombolysis were discussed with the patient and her family members. After obtaining written informed consent, the woman was thrombolysed with streptokinase. After 24 hours, tachycardia and tachypnea resolved, she became normotensive and was weaned off oxygen. Repeated 2D-Echo revealed normal right heart chamber dimensions and SPAP reduced to 30 mm Hg. The patient did not develop any vaginal bleeding. Ultrasound of pelvis did not disclose any intrauterine or pelvic collection.

Our report highlights the fact that in cases of high-risk pulmonary embolism, an absolute contraindication to thrombolysis might become a relative contraindication. Systemic thrombolysis can be lifesaving in such patients.
