Acute eosinophilic pneumonia associated with non-cigarette smoking products: a systematic review

Abstract

Acute eosinophilic pneumonia (AEP) is characterized by an acute onset febrile respiratory illness with bilateral chest infiltrates and evidence of pulmonary eosinophilia. Cigarette smoking is the main risk factor, but drugs and other inhalational exposures have also been reported. Herein, the association between AEP and smoking devices other than cigarettes is reviewed.

The PubMed database was searched using terms such as “smoking”, “vaping”, “e-cigarette”, “waterpipe”, and “marijuana”, along with other commonly used synonyms for these terms. In addition, eosinophilic lung diseases were also searched for using the same database. All cases of AEP were identified using the modified Philit criteria in association with the use of marijuana, waterpipe, e-cigarettes or heat-not-burn cigarettes. Cases associated with illicit drug use were excluded.

Twelve cases were included with a median age of 20 (15–60). 75% of patients studied were male. Exposures included marijuana smoking (n = 5), waterpipe usage (n = 2), heat-not-burn cigarette use (n = 2), e-cigarette use (n = 2) and synthetic cannabinoid use (n = 1). A recent change in smoking habits was reported in 50% of patients. Presenting symptoms were dyspnea (91.6%), cough (66.6%), fever (66.6%) and chest pain (25%). 90% of patients had leukocytosis on presentation, but only 16.6% had peripheral eosinophilia. The median eosinophil percentage in bronchoalveolar lavage was 67.5% (0 to 78). Two patients had a lung biopsy performed. Bilateral involvement on chest imaging was reported in all patients. Five patients (41.6%) required invasive mechanical ventilation and ten patients (83.3%) were treated in an intensive care unit. All patients responded to corticosteroid therapy with no relapses reported.

Acute eosinophilic pneumonia is reported with smoking that does not include traditional cigarette smoking such as waterpipes, e-cigarettes, heat-not-burn cigarettes, and marijuana and can have a similar presentation and clinical course.

Key words: eosinophilic pneumonia, smoking, e-cigarette, waterpipe, vaping, marijuana, cannabis

Adv Respir Med. 2020; 88: 142–146

Introduction

Acute eosinophilic pneumonia (AEP) is an eosinophilic lung disease characterized by an acute onset febrile respiratory illness with bronchoalveolar lavage eosinophilia that promptly responds to treatment with steroids. While the disease can be idiopathic, cigarette smoking is a major risk factor [1, 2] and commonly occurs in the setting of new exposure or a recent change in smoking habits [3, 4]. Drug use and other inhalational exposures are also known triggers [5–7]. Here, the reported cases of AEP in association with non-cigarette smoking such as e-cigarette, marijuana, and waterpipe smoking are reviewed.

Material and methods

The PubMed database was searched using the following keywords: smoking, electronic nicotine delivery systems, waterpipe, hookah, shisha, marijuana, cannabis, non-cigarette tobacco, vaping, e-cigarettes, electronic cigarettes and cannabis sativa. These keywords were searched for in combination with the following medical complications: eosinophilic pneumonia, respiratory distress syndrome, ARDS, respiratory insufficiency, and pulmonary eosinophilia. The “Related articles” section in PubMed was used to screen for additional relevant articles. The reference lists of the relevant articles were also screened to look
for other manuscripts eligible for the current review. Cases were included if they involved cases of AEP defined as: 1) Acute respiratory illness of 1-month duration or less; 2) Bilateral pulmonary infiltrates on chest imaging; 3) Eosinophilic pneumonia detected by Bronchoalveolar lavage (BAL) with eosinophils totaling more than 25% or showing eosinophilic pneumonia on lung biopsy. In addition, exposure to smoking items other than traditional cigarettes was required and included cannabis, electronic cigarettes, heat-not-burn cigarettes, waterpipes and hookahs. Cases with exposure to illicit drug use were excluded. The results of this search are summarized in Figure 1. 943 abstracts were reviewed and 42 of them were identified for full text review (in addition to one relevant report identified by screening the references of the reviewed articles). Two were excluded because of illicit drug use exposure and 29 articles were not relevant (review articles or no relevant exposure). Twelve cases met the inclusion criteria (Figure 1).

Results

Patient characteristics and exposures

Table 1 summarizes the reported cases and patient demographics. 12 cases of AEP linked to non-cigarette smoking were reported with the patients having a median age of 20 (range 15–60). 42.6% were younger or equal to 18 years of age and 75% were male. Exposures reported included patients who smoked marijuana (n = 5), used a waterpipe (n = 2), smoked heat-not-burn cigarettes (n = 2), used e-cigarettes (n = 2), and one who used synthetic cannabinoids (n = 1). 25% reported associated cigarette smoking. A recent change in smoking habits was reported in 50% of patients and included the following: new initiation within 1 month in one patient, recent product change in four patients, and restarting less than 1 month in 3 patients. One patient also reported starting cigarette smoking within 1 month of symptom onset. Time from the last inhalational exposure to onset of symptoms was reported in 5 cases; three of them occurred within 1 day, one occurred after 2 days, and one occurred after 2 weeks. Two patients reported comorbid asthma.

Clinical manifestations, laboratory and radiological findings

Patients presented with dyspnea (91.6%), cough (66.6%), fever (66.6%) and chest pain (25%). Lung auscultation findings were reported in 9 out of 12 patients and findings included crackles (55.5%) and wheezing (22.2%). White blood cell count (WBCs) was reported in 11 patients with a median of 19,95 × 10⁹/L (range 5.8 to 28) with 90% having leukocytosis as defined by WBC count greater than 11 × 10⁹ cells/L. Only 2 patients (16.6) had peripheral eosinophilia on presentation. Three additional patients (25%) developed peripheral eosinophilia during their hospitalization.

Bronchoalveolar lavage eosinophilic cell count was reported in 11 out of 12 patients. In one of the patients, the procedure had to be aborted due to hypoxemia which resulted in an inadequate sample. Of the remaining ten patients, the median eosinophil percentage was 67.5% (range 0 to 78) with 90% of patients having an eosinophil count totaling more than 25%. The only patient who had less than 25% (0 eosinophils) was treated with corticosteroids prior to bronchoscopy. One patient’s sputum was sent for evaluation and their eosinophil count was 14%. IgE levels were reported in 4 patients; they were normal in three patients and elevated in one. Lung biopsies were obtained in two patients and confirmed eosinophilic pneumonia. One of these biopsies was conducted using video assisted thoracoscopic surgery (VATS), while the other sampling method was not specified.

Bilateral involvement on chest imaging was reported in all patients. Computed tomography

Discussion

Acute eosinophilic pneumonia is a disease characterized by an acute respiratory illness with bilateral involvement on chest imaging, pulmonary eosinophilia and a prompt response to treatment with corticosteroids. It commonly progresses to respiratory failure requiring invasive mechanical ventilation and intensive care [1, 4, 20]. Philit et al. [21] suggested diagnostic criteria which required subsequent modifications [1, 4] seeing as hypoxemia is not present in all patients and recovery without steroids was reported. Cigarette smoking is a strong risk factor [1, 2] and patients frequently report recent initiation of smoking, a change in smoking habits [3, 4], drug use and/or other inhalational exposures [5, 6, 22, 23]. Non-cigarette forms of smoking are increasingly used. These include e-cigarettes [24, 25], waterpipe/hookah smoking [25–27], and marijuana use [28]. Younger populations are mainly at risk and include adolescents as well as college and university students [26, 29–31]. Recently, an outbreak of vaping induced lung injury was reported [32]. Other pulmonary effects of vaping include: bronchial toxicity [33], lipid pneumonia [34], diffuse alveolar hemorrhage [35], hypersensitivity pneumonitis [36], and organizing pneumonia [37]. In the current review, literature was researched for reported cases of AEP associated with these exposures. The median age in the
reviewed cases was 20 with 42% being 18 years of age or younger. This reflects the increasing use of such products by the young and adolescent population, and the need for public health policies and awareness to address this problem as they are frequently falsely perceived as safe by the public. In addition to the direct health consequences of these products, they increase the risk of traditional cigarette smoking in users [38]. As reported by Rhee et al. [4], the exposure to other types of smoking was frequently recently started or altered (50% of patients) similarly to traditional cigarette smokers. Fever was present in 66.6% of the patients, but higher percentages were reported in other studies (mean 80%) [1].

Peripheral eosinophilia was not common during presentation and this is a related finding to Giacomini et al. [5] who reported a lower incidence of peripheral eosinophilia in smoking associated AEP (36%) compared to other causes. Cigarette smoking and other types of smoking likely share common pathophysiological mechanisms which might explain why peripheral eosinophilia was uncommon upon presentation in this review similarly to smoking associated AEP. Like in other studies [1, 20], peripheral eosinophilia can arise during hospitalization (25% in the reviewed cases above). Bronchoalveolar lavage eosinophilia was present in most of the reviewed cases. One patient had no eosinophils on BAL, but the diagnosis of eosinophilic pneumonia was later confirmed by biopsy. In this patient, the BAL was done after corticosteroid therapy. In another patient, the procedure had to be aborted due to hypoxemia. The retrieved sample had an eosinophil count of 6% and biopsy obtained by VATS confirmed eosinophilic pneumonia but the sample was deemed ineligible due to the aforementioned complication during the procedure. One patient had sputum cytology showing eosinophilia without a reported BAL and responded promptly to corticosteroid therapy. Like other studies [1, 4], ground glass opacities (GGO) and bilateral infiltrates were the most common chest imaging findings. Pleural effusions were less common in the reviewed cases. Some radiological details might have been missed from the case reports. Invasive mechanical ventilation was required in 41.6% of patients. One patient required ECMO. Rates of mechanical ventilation are lower in AEP studies (mean 25%) [1]. This review included only case reports where there was a possibility of reporting bias where severe cases are reported more than milder ones. Different corticosteroid regimens were used with an excellent response in all patients. The regimens used varied and no conclusions can be drawn from these cases, but prior data in AEP associated with other causes showed that treatment duration could potentially be shortened to 2 weeks [4]. This review is limited by the quality of data available that comes mainly from case reports. Clinical, radiological and laboratory details might have been omitted. Also, reporting bias cannot be excluded as the exposure is sometimes not disclosed by patients.

Conclusion

AEP is reported with smoking outside of traditional cigarette smoking including vaping, waterpipe smoking, marijuana and HNBCs. The disease has a similar presentation and clinical course to AEP associated with cigarette smoking and other exposures.
