Drug-induced spatial dispersion of repolarization

Charles Antzelevitch
Masonic Medical Research Laboratory, Utica, NY, USA

Abstract
Spatial dispersion of repolarization in the form of transmural, trans-septal and apico-basal dispersion of repolarization creates voltage gradients that inscribe the J wave and T wave of the ECG. Amplification of this spatial dispersion of repolarization (SDR) underlies the development of life-threatening ventricular arrhythmias associated with inherited or acquired ion channelopathies giving rise to the long QT, short QT and Brugada syndromes (BrS). This review focuses on the role of spatial dispersion of repolarization in drug-induced arrhythmogenesis associated with the long QT and BrS. In the long QT syndrome, drug-induced amplification of SDR is often secondary to preferential prolongation of the action potential duration (APD) of M cells, whereas in the BrS, it is thought to be due to selective abbreviation of the APD of right ventricular epicardium. Among the challenges ahead is the identification of a means to quantitate SDR non-invasively. This review also discusses the value of the interval between the peak and end of the T wave (Tpeak–Tend, Tp–Te) as an index of SDR and transmural dispersion of repolarization, in particular. (Cardiol J 2008; 15: 100–121)

Key words: LQT syndrome, Brugada syndrome, spatial dispersion of repolarization, channelopathies

Introduction
Heterogeneities of ventricular repolarization have long been implicated in arrhythmogenesis. It is well established that ventricular myocardium is comprised of at least three electrophysiologically and functionally distinct cell types: epicardial, M and endocardial cells [1, 2]. These three principal ventricular myocardial cell types differ with respect to phase 1 and phase 3 repolarization characteristics. Ventricular epicardial and M, but not endocardial, cells generally display a prominent phase 1, due to a large 4-aminopyridine (4-AP) sensitive transient outward current (Ito), giving the action potential a spike and dome or notched configuration. These regional differences in Ito, first suggested on the basis of action potential data [3], have now been directly demonstrated in canine [4], feline [5], rabbit [6], rat [7], and human [8, 9] ventricular myocytes.

Differences in the magnitude of the action potential notch and corresponding differences in Ito have also been described between right and left ventricular epicardial and M cells [10, 11]. This distinction is thought to form the basis for why the Brugada syndrome (BrS), a channelopathy-mediated form of sudden death, is a right ventricular disease.

Between surface epicardial and endocardial layers are layers of transitional and M cells. M cells are distinguished by the ability of their action potential to prolong disproportionately relative to the action potential of other ventricular myocardial cells in response to a slowing of rate and/or in response to action potential duration (APD)-prolonging agents [1, 12, 13]. In the dog, the ionic basis for these features of the M cell include the presence of a smaller slowly activating delayed rectifier current (Iks) [14], a larger late sodium current (late INa) [15] and a larger Na–Ca exchange current (INa,Ca) [16].
In the canine heart, the rapidly activating delayed rectifier (I_{Kr}) and inward rectifier (I_{K1}) currents are similar in the three transmural cell types. Transmural and apico-basal differences in the density of I_{ks} channels have been described in the ferret heart [17]. I_{ks} message and channel protein are much larger in the ferret epicardium. I_{ks} is larger in M cells isolated from the right vs. left ventricles of the dog [11]. Calcium current (I_{Ca}) has been shown to be similar among cells isolated from epicardium, M, and endocardial regions of the left ventricular wall [18, 19]. One study however reported differences in Ca^{2+} channel properties between epicardial and endocardial canine ventricular cells with endocardial display of a larger current [20].

The distribution of M cells within the ventricular wall has been investigated in greatest detail in the left ventricle of the canine heart. Although transitional cells are found throughout the wall in the canine left ventricle, M cells displaying the longest action potentials [at basic cycle lengths (BCLs) ≥ 2000 ms] are often localized in the deep subendocardium to midmyocardium in the anterior wall [21], deep subepicardium to midmyocardium in the lateral wall [12] and throughout the wall in the region of the right ventricular (RV) outflow tracts [2]. M cells are also present in the deep cell layers of endocardial structures, including papillary muscles, trabecule and the interventricular septum [22]. Unlike Purkinje fibers, M cells are not found in discrete bundles or islets [22, 23], although there is evidence that they may be localized in discrete muscle layers. Cells with the characteristics of M cells have been described in the canine, guinea pig, rabbit, pig and human ventricles [4, 12–14, 21–41].

Transmural, trans-septal and apico-basal heterogeneities of final repolarization of the action potential within ventricular myocardium are thought to be responsible for inscription of the T wave [39, 42]. Studies involving the arterially-perfused wedge have shown that currents flowing down voltage gradients on either side of the M region are in large part responsible for the T wave [39]. The interplay between these opposing forces establishes the height and width of the T wave and the degree to which either the ascending or descending limb of the T wave is interrupted, leading to a bifurcated or notched appearance of the T wave [39]. The voltage gradients result from a more positive plateau potential in the M region than in epicardium or endocardium as well as from differences in the time-course of phase 3 of the action potential of the three predominant ventricular cell types.

Under normal, and most long QT conditions, the epicardial response is the earliest to repolarize and the M cell action potential is often the last. Full repolarization of the epicardial action potential is coincident with peak of the T wave and repolarization of the M cells coincides with the end of the T wave. Thus, the repolarization of the M cells in the heart usually determine the QT interval. The interval between the peak and end of the T wave (T_{p}–T_{e}) has been suggested to provide an index of transmural dispersion of repolarization, which may be of prognostic value [39, 43].

Although apico-basal repolarization gradients have been suggested to play a prominent role in the registration of the T wave, particularly T waves changes associated with cardiac memory [42, 44] studies involving coronary-perfused wedge preparations suggest little or no contribution under baseline conditions and greater contribution of global dispersion of repolarization to T wave changes associated with cardiac memory [39, 45].

The long QT syndrome

Prolongation of the action potential duration of the M cell usually underlies the prolongation of the QT interval on the surface ECG, the time interval between ventricular depolarization and repolarization. Prolongation of the QT can occur as a consequence of congenital defects or in response to drugs that prolong the APD via a reduction in I_{ks}, I_{kr} or the inward rectifier potassium current (I_{K1}), or an increase in calcium current (I_{Ca}) or late sodium current (I_{Na}). The inherited forms of the long QT syndrome (LQTS) are phenotypically and genotypically diverse, but have in common the appearance of long QT interval in the ECG, an atypical polymorphic ventricular tachycardia known as torsade de pointes (TdP), and, in many but not all cases, a relatively high risk for sudden cardiac death [46–48]. Congenital LQTS is subdivided into ten genotypes distinguished by mutations in at least seven different ion genes and in structural anchoring protein located on chromosomes 3, 4, 6, 7, 11, 17 and 21 (Table 1) [49–56]. Timothy syndrome, also referred to as LQT8, is a rare congenital disorder characterized by multi-organ dysfunction including prolongation of the QT interval, lethal arrhythmias, webbing of fingers and toes, congenital heart disease, immune deficiency, intermittent hypoglycemia, cognitive abnormalities, and autism. Timothy syndrome has been linked to loss of voltage-dependent inactivation due to mutations in Ca_{1.2}, the gene that encodes for an α subunit of the calcium channel [57]. The most recent genes associated with LQTS are CAV3

Charles Antzelevitch, Drug-induced TDR
which encodes caveolin-3 and SCN4B which encodes Na\textsubscript{B}4, an auxiliary subunit of the cardiac sodium channel. Mutations in both genes produce a gain of function in late I\textsubscript{Na}, causing an LQT3-like phenotype [55, 56].

Two patterns of inheritance have been identified: 1) a rare autosomal recessive disease associated with deafness (Jervell and Lange-Nielsen), caused by 2 genes that encode for the slowly activating delayed rectifier potassium channel (KCNQ1 and KCNE1); and 2) a much more common autosomal dominant form known as the Romano-Ward syndrome, caused by mutations in 10 different genes, including KCNQ1 (KvLQT1; LQT1); KCNH2 (HERG;LQT2); SCN5A (Na\textsubscript{1.5}; LQT3); ANKB (LQT4); KCNE1 (minK; LQT5); KCNE2 (MiRP1; LQT6); KCNJ2 (LQT7; Andersen’s syndrome), CACNA1C (Ca\textsubscript{1.2}; LQT8; Timothy syndrome), CAV3 (Caveolin-3; LQT9) and SCN4B (Na\textsubscript{B}4, LQT10). Six of the 10 genes encode for cardiac potassium channels, one for the cardiac sodium channel (SCN5A), one for the $\beta$ subunit of the sodium channel, one for caveolin-3 and one for a protein called Ankyrin B (ANKB), which is involved in anchoring of ion channels to the cellular membrane.

Acquired LQTS refers to a syndrome similar to the congenital form but caused by exposure to drugs that prolong the duration of the ventricular action potential [58] or QT prolongation secondary to cardiomyopathies such as dilated or hypertrophic cardiomyopathy, as well as to abnormal QT prolongation associated with bradycardia or electrolyte imbalance [59–63].

Table 2 presents a list of drugs known to prolong the QT interval and to induce torsade de pointes. Most of these drugs block I\textsubscript{Kr}, many also block I\textsubscript{Ks}, and some augment late I\textsubscript{Na}, so that in many ways they are similar to congenital forms of LQTS. The acquired form of the disease is far more prevalent than the congenital form, and in some cases may have a genetic predisposition.

The ability of genetic mutations and drugs to amplify spatial dispersion of repolarization within the ventricular myocardium has been identified as the principal arrhythmogenic substrate in both acquired and congenital LQTS. Early- and in some cases delayed-afterdepolarizations have been identified as triggers responsible for the precipitation of torsade de pointes. The accentuation of spatial dispersion, typically secondary to an increase of transmural, trans-septal or apico-basal dispersion of repolarization, and the development of early afterdepolarization (EAD)-induced triggered activity underlie the substrate and trigger for the development of torsade de pointes arrhythmias observed under LQTS conditions [64, 65]. Models of the LQT1, LQT2, LQT3, LQT5, LQT6, LQT7 and LQT8 forms of the long QT syndrome have been developed using the canine arterially perfused left ventricular wedge preparation [66–69]. These models suggest that in LQT1–3, 4, and 8 preferential prolongation of the M cell APD can lead to an
increase in the QT interval as well as an increase in transmural dispersion of repolarization (TDR), which contributes to the development of spontaneous as well as stimulation-induced TdP [32, 37, 70].

The distinctive characteristics of the M cells are at the heart of the long QT syndrome. The hallmark of the M cell is the ability of its action potential to prolong more than that of epicardium or endocardium in response to a slowing of rate [2, 12, 71]. As previously detailed, this feature of the M cell is due to weaker repolarizing current during phases 2 and 3 secondary to a smaller IKs and a larger late INa and INa–Ca [14–16] compared to epicardial and endocardial cells. These ionic distinctions sensitize the M cells to a variety of pharmacological agents and pathophysiological states. Agents that block IKr, IKs or increase ICa or late INa generally produce a much greater prolongation of the APD of the M cell than of epicardial or endocardial cells.

Experimental models that mimic the clinical congenital syndromes with respect to prolongation of the QT interval, T wave morphology, rate dependence of QT have also been helpful in elucidation of the basis for sympathetic nervous system influences [21, 32, 37–39].

IKs block using chromanol 293B is used to mimic LQT1. IKs block alone produces a homogeneous prolongation of repolarization and refractoriness across the ventricular wall and does not induce arrhythmias. The addition of isoproterenol causes abbreviation of epicardial and endocardial APD but a prolongation or no change in the APD of the M cell, resulting in a marked augmentation of TDR and the development of spontaneous stimulation-induced TdP [37]. These changes give rise to a broad-based T wave and the long QT interval characteristics of LQT1. The development of TdP in the model requires β adrenergic stimulation, consistent with a high sensitivity of congenital LQTS, LQT1 in particular, to sympathetich stimulation [46–48, 72, 73].

IKr block using d-Sotalol has been used to mimic LQT2 and provides a model of the most common form of acquired (drug-induced) LQTS. A greater prolongation of the M cell action potential and slowing of phase 3 of the action potential of all three cell types results in a low amplitude T wave, long
QT interval, large transmural dispersion of repolarization and the development of spontaneous as well as stimulation-induced TdP. The addition of hypokalemia gives rise to low-amplitude T waves with a deeply notched or bifurcated appearance, similar to those commonly seen in patients with the LQT2 syndrome [32, 39]. Isoproterenol further exaggerates transmural dispersion of repolarization, thus increasing the incidence of TdP [70].

ATX-II, an agent that increases late INa, is used to mimic LQT3 [32]. ATX-II markedly prolongs the QT interval, delays the onset of the T wave, in some cases also widening it, and produces a sharp rise in transmural dispersion of repolarization as a result of a greater prolongation of the APD of the M cell. The differential effect of ATX-II to prolong the M cell action potential is likely due to the presence of a larger late sodium current in the M cell [15]. ATX-II produces a marked delay in onset of the T wave because of a relatively large effect of the drug on epicardial and endocardial APD. This feature is consistent with the late-appearing T wave (long isoelectric ST segment) observed in patients with the LQT3 syndrome. Also in agreement with the clinical presentation of LQT3, the model displays a steep rate dependence of the QT interval and develops TdP at slow rates. Interestingly, β adrenergic influence in the form of isoproterenol reduces transmural dispersion of repolarization by abbreviating the APD of the M cell more than that of epicardium or endocardium, and thus reducing the incidence of TdP. While the beta-adrenergic blocker propranolol is protective in LQT1 and LQT2 wedge models, it has the opposite effects in LQT3, acting to amplify transmural dispersion and promoting TdP [70].

It is interesting that the response to sympathetic activation displays a very different time-course in the case of LQT1 and LQT2, both in experimental models and in the clinic [65, 74]. In LQT1, β adrenergic stimulation induces an increase in TDR that is most prominent during the first two minutes, but which persists, although to a lesser extent, during steady-state. Torsade de points incidence is enhanced during the initial period as well as during steady-state. In LQT2, isoproterenol produces only a transient increase in TDR that persists for less than 2 minutes. Torsade de points incidence is therefore enhanced only for a brief period of time. These differences in time-course may explain the important differences in autonomic activity and other gene-specific triggers that contribute to events in patients with different LQTS genotypes [65, 73, 75].

Figure 1 presents a working hypothesis for our understanding of the mechanisms underlying LQTS-related TdP based on available data. The hypothesis presumes the presence of electrical heterogeneity in the form of transmural or transseptal dispersion of repolarization under baseline conditions and the amplification of TDR by agents that reduce net repolarizing current via a reduction...
in $I_{K_s}$ or $I_{K_r}$ or augmentation of $I_{Ca}$ or late $I_{Na}$. Conditions that cause a reduction in $I_{K_s}$ or augmentation of late $I_{Na}$ lead to a preferential prolongation of the M cell action potential. As a consequence, the QT interval prolongs and is accompanied by a dramatic increase in transmural dispersion of repolarization, thus creating a vulnerable window for the development of reentry. The reduction in net repolarizing current also predisposes to the development of EAD-induced triggered activity in M and Purkinje cells, which provide the extrasystole that triggers TdP when it falls within the vulnerable period. Beta-adrenergic agonists further amplify transmural heterogeneity (transiently) in the case of $I_{K_s}$ block, but reduce it in the case of $I_{K_r}$ agonists [30, 70].

Although conditions that prolong QT are often associated with an increase in TDR, this is not always the case. Amiodarone, a potent antiarrhythmic agent used in the management of both atrial and ventricular arrhythmias, is rarely associated with TdP [76]. Chronic administration of amiodarone produces a greater prolongation of APD in epicardium and endocardium, but less of an increase in APD, or even a decrease at slow rates, in the M region, thereby reducing TDR [77]. In a dog model of chronic complete atrioventricular block and acquired LQTS, 6 weeks of amiodarone was shown to produce a major QT prolongation without producing TdP. In contrast, after 6 weeks of dronedarone, TdP occurred in 4 of 8 dogs displaying the highest spatial dispersion of repolarization (105 ± 20 ms) [78]. Sodium pentobarbital is another agent that prolongs the QT interval but reduces TDR. Pentobarbital has been shown to produce a dose-dependent prolongation of the QT interval, accompanied by a reduction in TDR from 51 to 27 ms [36]. TdP is not observed under these conditions. Nor can it be induced with programmed stimulation. Amiodarone and pentobarbital have in common the ability to block $I_{K_s}$, $I_{K_r}$, and late $I_{Na}$. This combination produces a preferential prolongation of the APD of epicardium and endocardium so that the QT interval is prolonged, but TDR is actually reduced and TdP does not occur.

Cisapride, another agent that blocks both inward and outward currents, produces a biphasic concentration-dependent prolongation of the QT interval. A parallel biphasic dose-response relationship is seen for TDR, peaking at 0.2 μM, and it is only at this concentration that TdP is observed. Higher concentrations of cisapride further prolong QT, but reduced TDR, thereby preventing TdP induction [79]. This finding suggests that the spatial dispersion of repolarization is more important than the prolongation of the QT interval in determining the substrate for TdP.

The $I_{K_s}$ blocker, chromanol 293B, is another agent that increases QT without augmenting TDR. Chromanol 293B prolongs APD of the 3 cell types homogeneously, neither increasing TDR nor widening the T wave. TdP is not observed under these conditions. Although an arrhythmogenic substrate is not present with $I_{K_s}$ block alone, it develops very quickly with the introduction of β-adrenergic stimulation. Isoproterenol abbreviates the APD of epicardial and endocardial cells but not that of the M cell, resulting in a marked accentuation of TDR [70]. Torsade de pointes readily develops under these conditions.

Thus, QT prolonging agents display very different concentration-dependent behavior. Pure $I_{K_s}$ blockers such as sotalol, dofetilide and erythromycin produce a dose-dependent prolongation of the QT interval that is associated with a dose-dependent prolongation of TDR. When TDR reaches the threshold for re-entry, which in the canine wedge preparation is approximately 90 ms, TdP will occur. With more complex agents such as quinidine and cisapride there is a biphasic dose-response relationship. TDR parallels QT, but the two can peak at different concentrations. TdP occurs when and if TDR reaches the threshold value. Still other drugs produce a dose-dependent prolongation of QT, but a smaller increase or even a decrease in TDR; threshold values for TdP are rarely reached. Finally, agents that preferentially block $I_{Na}$, such as chromanol 293B, and agents with multiple ion channel effects including pentobarbital, amiodarone, and the new anti-anginal agent ranolazine, produce a dose-dependent prolongation of the QT interval that is not associated with an increase in TDR. Torsade de pointes rarely, if ever, occurs under these conditions.

Thus, TdP is not produced by drugs that cause a dose-dependent prolongation of QT but a reduction of TDR or little or no increase in TDR. Taken together these findings indicate that arrhythmogenesis in the long QT syndromes is not due to prolongation of QT interval but rather to the increase
in TDR that often accompanies prolongation of the QT interval. The ability of sympathetic influences to dramatically increase TDR also explains why LQT1 and LQT2 patients are so sensitive to sympathetic stimulation.

**Tpeak–Tend as a non-invasive marker of spatial dispersion of repolarization**

If QT prolongation is not prognostic of risk for the development of life-threatening arrhythmias is there a better index? While a number of promising approaches have been pursued in recent years, our interest has been in the interval between the peak and the end of the T wave (Tpeak–Tend interval). Differences in the time-course of repolarization of these three predominant ventricular myocardial cell types contribute prominently to the inscription of the electrocardiographic T wave recorded in the precordial leads [39]. These differences in action potential morphology lead to the development of opposing voltage gradients on either side of the M region, which contribute to inscription of the T wave, especially those inscribed in the precordial leads (Fig. 1) [39]. Apico-basal gradients are thought to contribute to the T wave as well, especially in the limb lead where the polarity of the T wave may be opposite to that recorded in the precordial leads [42]. The interplay between these opposing transmural forces determines the height and width of the T wave and the extent to which the T wave may be interrupted, resulting in a bifid or notched appearance.

When the T wave is upright, the epicardial response is the earliest to repolarize and the M cell action potential is the last. Full repolarization of the epicardial action potential coincides with the peak of the T wave and repolarization of the M cells is coincident with the end of the T wave. It therefore follows that the duration of the M cell action potential determines the QT interval, whereas the duration of the epicardial action potential determines the QT peak interval. Another interesting finding stemming from these studies was that the Tpeak–Tend interval may provide an index of transmural dispersion of repolarization [2, 39]. Figure 2 illustrates these relationships under baseline and long QT conditions. ATX-II, a sea anemone toxin, mimics the LQT3 form of the long QT syndrome by augmenting the late sodium current, which helps to sustain the plateau of the action potential. ATX-II, like most agents that prolong the action potential, causes a preferential prolongation of the M cell response, thus producing a dramatic accentuation of the transmural dispersion of repolarization, which is reflected on the ECG as a prolongation of the Tpeak–Tend interval. An increase in transmural dispersion of repolarization is a common feature of all LQTS models and has been shown to provide the substrate for the development of TdP under long QT conditions [2, 32, 70].

Based on these and similar studies, the Tpeak–Tend interval in precordial ECG leads was suggested to provide an index of transmural dispersion of repolarization [2]. More recent studies have also provided guidelines for the estimation of transmural dispersion of repolarization in the case of more complex T waves, including negative, biphasic and triphasic T waves [80]. In such cases, the interval from the nadir of the first component of the T wave to the end of the T wave was shown to provide an electrocardiographic approximation of TDR.

While these relationships are relatively straightforward in the coronary-perfused wedge preparation, extrapolation to the surface ECG recorded *in vivo* must be approached with great caution and will require careful validation. The Tpeak–Tend interval is unlikely to provide an absolute measure of transmural dispersion *in vivo*, as demonstrated by Xia et al. [81]. However, changes in this parameter are thought to be capable of reflecting changes in spatial dispersion of repolarization, including TDR, and thus may be prognostic of arrhythmic risk under a variety of conditions [82–87]. Takenaka et al. [86] recently demonstrated exercise-induced accentuation of the Tpeak–Tend interval in LQT1 patients. These observations coupled with those of Schwartz et al. [75], demonstrating an association between exercise and risk for TdP in LQT1 patients, pointed to the potential value of Tpeak–Tend in forecasting risk for the development of torsade de pointes. Direct evidence in support of Tpeak–Tend as an index to predict TdP in patients with LQTS has recently been provided by a number of studies. Yamaguchi et al. [88] showed that Tpeak–Tend is more valuable than QTc and QT dispersion as a predictor of TdP in patients with acquired LQTS. Shimizu et al. [85] demonstrated that Tpeak–Tend but not QTc, predicted sudden cardiac death in patients with hypertrophic cardiomyopathy. In a case-controlled study comparing 30 cases of acquired bradyarrhythmias complicated by TdP and 113 cases with uncomplicated bradyarrhythmias, Topilski et al. [89] found that QT, QTc and Tpeak–Tend intervals were strong predictors of TdP, with the best single discriminator being a prolonged Tpeak–Tend. Watanabe et al. [87] demonstrated that prolonged Tpeak–Tend is associated with inducibility as well as spontaneous...
development of ventricular tachycardia (VT) in high risk patients with organic heart disease.

These interesting studies demonstrating an association between an increase in T_peak–T_end and arrhythmic risk notwithstanding, direct validation of Tpeak–Tend measured at the body surface as an index of TDR is still lacking. Guidelines for such validation have been suggested [39, 80, 90]. Because precordial leads view the electrical field across the ventricular wall, T peak–Tend would be expected to be most representative of TDR in these leads. The precordial leads are unipolar leads placed on the chest that are referenced to Wilson central terminal. The direction of these leads is radially toward the “center” of the heart, the center of the Einthoven triangle. Unlike the precordial leads, the bipolar limb leads, including leads I, II, and III, do not look across the ventricular wall. While T_peak–T_end intervals measured in these limb leads may provide an index of TDR, they are more likely to reflect global dispersion, including apico-basal and interventricular dispersion of repolarization [81, 91].

A large increase in TDR is likely to be arrhythmogenic because the dispersion of repolarization and refractoriness occurs over a very short distance (the width of the ventricular wall), creating a steep repolarization gradient [92, 93]. It is the steepness of the repolarization gradient rather than the total magnitude of dispersion that determines its arrhythmogenic potential [92, 93]. Apico-basal or interventricular dispersion of repolarization is less informative because it may or may not be associated with a steep repolarization gradient and thus may or may not be associated with arrhythmic risk.

Another important consideration is that TDR can be highly variable in different regions of the ventricular myocardium, particularly under pathophysiologic conditions. Consequently, it is important to measure T_peak–T_end independently in each of the precordial leads and it is inadvisable to average T_peak–T_end among several leads [81]. Yamaguchi et al. [88] in their study of acquired LQTS targeted lead V5. In contrast, because BrS is a right
ventricular disorder, Castro et al. [94] targeted lead V2 in their study of \( T_{\text{peak}} - T_{\text{end}} \) in BrS.

The criteria suggested for validation of \( T_{\text{peak}} - T_{\text{end}} \) as an index of TDR therefore include a requirement 1) that individual precordial leads, and not bipolar limb leads, be evaluated; and 2) that TDR be present at baseline and significantly augmented as a result of an intervention.

The quest for direct validation or invalidation of \( T_{\text{peak}} - T_{\text{end}} \) measured at the body surface as an index of TDR based on these fundamental criteria remains unfulfilled [91]. Although most studies to date concur that \( T_{\text{peak}} - T_{\text{end}} \) provides a measure of spatial dispersion of repolarization, the extent to which an augmented \( T_{\text{peak}} - T_{\text{end}} \) interval is prognostic of arrhythmic risk depends on the proximity of the regions displaying disparate repolarization times (i.e., repolarization gradient). Consequently, it would be helpful to know to what extent \( T_{\text{peak}} - T_{\text{end}} \) provides an index of TDR, in which case the differences in refractoriness are likely to be within close proximity. An ideal model in which to test the hypothesis is in the chronic atrioventricular (AV) block dog treated with a Class III antiarrhythmic agent, since changes in \( T_{\text{peak}} - T_{\text{end}} \) could be correlated with TDR in a model that displays prominent TDR, and additionally correlated with the risk for development of TdP.

In addition to pharmacologic agents and pathophysiological states, interventions that reverse the direction of activation of the ventricular wall can augment TDR. In the example illustrated in Figure 3, reversing the direction of activation of the ventricular wall in the arterially-perfused left ventricular wedge preparation is shown to lead to a broader and taller T wave. TDR and \( T_{\text{peak}} - T_{\text{end}} \) are conspicuously augmented. In the presence of cisapride, reversing the direction of activation of the left ventricular (LV) wall, amplifies TDR sufficiently to permit the development of torsade de pointes [79]. Figure 4 shows that similar changes in the T wave are recorded in the human heart \textit{in vivo} when the direction of transmural activation is reversed [95]. Patients with heart failure were initially paced from an endocardial site facing lead V5–V6 and then from an adjacent site on the epicardial surface. The shift from endocardial to epicardial pacing led to a dramatic increase in TDR and \( T_{\text{peak}} - T_{\text{end}} \), similar to the changes observed in the wedge preparation. In 4 patients, \( T_{\text{peak}} - T_{\text{end}} \) increased by an average of 24.3%. These data provide evidence in support of
important transmural distinctions in repolarization across the ventricular wall, for such a change would not be observed if transmural repolarization was homogeneous, as suggested by some studies [42, 91, 96, 97].

A clinical consequence of the increase in TDR following reversal of the direction of activation of the ventricular wall was demonstrated by Medina-Ravell et al. [98]. These authors reported the first case in which an upgrade to biventricular pacing in a patient undergoing resynchronization therapy led to the development of torsade de pointes. Pacing via the endocardial electrode in the right ventricular apex was uneventful. In contrast, pacing via the left ventricular epicardial lead in the coronary sinus resulted in an increase in both QT interval and Tpeak–Tend, and the development of torsade de pointes. The available data suggest that epicardial activation of the LV wall during resynchronization therapy is a potential iatrogenic factor in a small subset of patients with prolonged QT intervals and/or in which TDR is prolonged [95].

**Brugada syndrome**

In that the BrS is believed to be secondary to an exaggeration of the J wave, it seems appropriate to first discuss the basis for the J wave of the ECG. The presence of a prominent action potential notch in epicardium but not endocardium gives rise to a transmural voltage gradient during ventricular activation that manifests as a late delta wave following the QRS or what more commonly is referred to as a J wave [99] or Osborn wave. A distinct J wave is often observed under baseline conditions in the ECG of some animal species, including dogs and baboons. Humans more commonly display a J point elevation rather than a distinct J wave. A prominent J wave in the human ECG is considered pathognomonic of hypothermia [100–102] or hypercalcemia [103, 104].

A transmural gradient in the distribution of Ito is responsible for the transmural gradient in the magnitude of phase 1 and action potential notch, which in turn gives rise to a voltage gradient across the ventricular wall responsible for the inscription of the J wave or J point elevation in the ECG [3, 4, 105]. Direct evidence in support of the hypothesis that the J wave is caused by a transmural gradient in the magnitude of the Ito-mediated action potential notch derives from experiments conducted in the arterially-perfused right ventricular wedge preparation showing a correlation between the amplitude of the epicardial action potential notch and that of the J wave recorded during interventions that alter the appearance of the electrocardiographic J wave, including hypothermia, premature stimulation (restitution), and block of Ito by 4-aminopyridine (4-AP) [99].

The molecular basis for the transmural distribution of Ito has long been a subject of debate.

---

**Figure 4.** Schematic representation of right ventricular epicardial action potential changes proposed to underlie the electrocardiographic manifestation of the Brugada syndrome. Modified from [173], with permission.
The transmural gradient of I_{\text{to}} in dog has been ascribed to a transmural distribution of KCND3 gene (Kv4.3), which encodes the a subunit of the I_{\text{to}} channel [106] and a transmural gradient of KChIP2, a \( \beta \) subunit that coassembles with and serves as a chaperone for Kv4.3 [107]. The steep transmural gradient of I_{\text{to}} suggests that spatial patterning of I_{\text{to}} is highly regulated in mammalian cardiac myocytes. However, very little is known about transcriptional regulation of I_{\text{to}} and its components. Recently, a transcriptional factor, Iroquois 5, was described and shown to regulate KCND2 expression [108]. The Iroquois homeobox (Irx) genes encode a conserved family of transcription factors that specify the identity of diverse territories in the heart. One of the members of this family, the homeodomain transcription factor 5 (IRX5), has been shown to contribute to the cardiac repolarization gradient. IRX5 causes repression of Kv4.2 expression by recruiting mBop (a cardiac transcriptional repressor), thus forming an inverse I_{\text{to}} gradient that contributes to coordinated contraction of the ventricular wall [18]. In the canine heart, IRX5 is also expressed in an endocardial-to-epicardial gradient, suggesting that it may regulate expression of KChIP2 and/or KCND3 genes.

Myocytes isolated from the epicardial region of the left ventricular wall of the rabbit show a higher density of cAMP-activated chloride current when compared to endocardial myocytes [109]. I_{\text{to}}, initially ascribed to a K⁺ current, is now thought to be primarily due to the calcium-activated chloride current (I_{\text{CICCl}}) as also thought to contribute to the action potential notch, but it is not known whether this current, differs among the three ventricular myocardiial cell types [110].

Transmural activation within the relatively thin wall of RV is relatively rapid causing the J wave to be buried inside the QRS. Thus, although the action potential notch is most prominent in right ventricular epicardium, right ventricular myocardium would be expected to contribute relatively little to the manifestation of the J wave under normal conditions. These observations are consistent with the manifestation of the J wave in ECG leads in which the mean vector axis is transmurally oriented across the left ventricle and septum. Accordingly, the J wave in the dog is most prominent in leads II, III, aVR, aVF, and mid to left precordial leads V3 through V6. A similar picture is seen in the human ECG [104, 111]. In addition, vectorcardiography indicates that the J wave forms an extra loop that occurs at the junction of the QRS and T loops [112]. It is directed leftward and anteriorly, which explains its prominence in leads associated with the left ventricle.

To our knowledge, the first description of the J wave was in the 1920s in animal experiments involving hypercalcemia [103]. The first extensive description and characterization appeared 30 years later by Osborn [113] in a study involving experimental hypothermia in dogs. The appearance of a prominent J wave in the clinic is typically associated with pathophysiological conditions, including hypothermia [100, 111] and hypercalcemia [103, 104]. The prominent J wave induced by hypothermia is the result of a marked accentuation of the spike-and-dome morphology of the action potential of M and epicardial cells (i.e., an increase in both width and magnitude of the notch). In addition to inducing a more prominent notch, hypothermia produces a slowing of conduction which permits the epicardial notch to clear the QRS so as to manifest a distinct J wave. Hypercalcemia-induced accentuation of the J wave [103, 104, 114] may also be explained on the basis of an accentuation of the epicardial action potential notch, possibly as a result of an augmentation of the calcium-activated chloride current and a decrease in I_{\text{to}} [115]. Accentuation of the action potential notch also underlies the electrocardiographic and arrhythmogenic manifestations of the BrS.

The Brugada syndrome is characterized by an accentuated ST segment elevation or J wave appearing principally in the right precordial leads (V1–V3), often followed by a negative T wave. The syndrome, first described in 1992, is generally associated with a high incidence of sudden cardiac death secondary to a rapid polymorphic VT or ventricular fibrillation (VF) [116]. The average age at the time of initial diagnosis or sudden death is 40 ± 22. The youngest patient diagnosed with the syndrome is 2 days of age, and the oldest is 84.

The prevalence of the BrS is estimated at 1–5 per 10,000 inhabitants worldwide. The frequency is lower in western countries and higher (≥ 5 per 10,000) in Southeast Asia, especially Thailand and the Philippines where BrS is considered to be the major cause of sudden death in young individuals. In these countries, the syndrome is often referred to as sudden unexplained nocturnal death syndrome (SUNDS) [117, 118].

Brugada syndrome is inherited via an autosomal dominant mode of transmission. The first gene to be linked to the BrS is SCN5A, the gene encoding for the a subunit of the cardiac sodium channel gene [119]. Mutations in SCN5A are also responsible for the LQT3 form of the long QT syndrome and cardiac conduction disease. A number of mutations have been reported to cause overlapping
syndromes; in some cases all three phenotypes are present [120].

Over one hundred mutations in SCN5A have been linked to the syndrome in recent years (see [121] for references; also see www.fsm.it/cardmoc). Only a fraction of these mutations have been studied in expression systems and shown to result in loss of function due either to: 1) failure of the sodium channel to express; 2) a shift in the voltage- and time-dependence of sodium channel current ($I_{Na}$) activation, inactivation or reactivation; 3) entry of the sodium channel into an intermediate state of inactivation from which it recovers more slowly or 4) accelerated inactivation of the sodium channel. In in vitro expression systems, the premature inactivation of the sodium channel is sometimes observed at physiological temperatures, but not at room temperature [122]. Acceleration of $I_{Na}$ inactivation was still more accentuated at higher than physiological temperatures, suggesting that the syndrome may be unmasked, and that patients with the BrS may be at an increased risk, during a febrile state [122]. A number of Brugada patients displaying fever-induced polymorphic VT have been identified since the publication of this report [123–125].

Mutation in the SCN5A gene account for approximately 18–30% of BrS cases. A higher incidence of SCN5A mutations has been reported in familial than in sporadic cases [133]. Of note, negative SCN5A results generally do not rule out causal gene mutations, since the promoter region, cryptic splicing mutations or presence of gross rearrangements are generally not part of routine investigation. A recent report by Hong et al. [134] provided the first report of a dysfunctional sodium channel created by an intronic mutation giving rise to cryptic splice site activation in SCN5A in a family with the BrS. The deletion of fragments of segments 2 and 3 of Domain IV of SCN5A caused complete loss of function.

Bezzina et al. [135] recently provided interesting evidence in support of the hypothesis that a SCN5A promoter polymorphism common in Asians modulates variability in cardiac conduction, and may contribute to the high prevalence of BrS in the Asian population. Sequencing of the SCN5A promoter identified a haplotype variant consisting of 6 polymorphisms in near-complete linkage disequilibrium that occurred at an allele frequency of 22% in Asian subjects and was absent in whites and blacks. The results of the study demonstrate that sodium channel transcription in the human heart may vary considerably among individuals and races and be associated with variable conduction velocity and arrhythmia susceptibility.

A second locus on chromosome 3, close to but distinct from SCN5A, has been linked to the syndrome [136] in a large pedigree in which the syndrome is associated with progressive conduction disease, a low sensitivity to procainamide, and a relatively good prognosis. The gene was recently identified as The glycerol-3-phosphate dehydrogenase 1-like Gene (GPD1L). A mutation in GPD1L has been shown to result in a partial reduction of $I_{Na}$ [137].

The third and fourth genes associated with the BrS were reported earlier this year and shown to encode the $\alpha_1$ (CACNA1C) and $\beta$ (CACNB2b) sub-units of the L-type cardiac calcium channel. Mutations in the $\alpha$ and $\beta$ subunits of the calcium channel can also lead to a shorter than normal QT interval, creating a new clinical entity consisting of a combined Brugada/short QT syndrome [138].

We are currently on a very steep learning curve in our understanding of the genotype-phenotype relationship in BrS and the role of genetics in the assignment of risk. It is recommended that all BrS patients, particularly symptomatic patients, undergo genetic screening. The argument for genetic testing is especially compelling in the case of BrS because the clinical manifestations of BrS generally appear later in life, in some cases resulting in sudden death without any warning. Risk stratification of younger family members is best achieved by genetic screening. Identification of mutation carriers among family members of symptomatic probands alerts the physician to closely follow these individuals and to proceed with the implantation of an implantable cardiac defibrillator (ICD) or other therapy if and when appropriate.

Amplification of epicardial and transmural dispersion of repolarization secondary to the presence of genetic defects, pathophysiologic factors and pharmacologic influences, leads to accentuation of the J wave and eventually to loss of the action potential dome, giving rise to extrasystolic activity in the form of phase 2 reentry. Activation of $I_n$ leads to a paradoxical prolongation of APD in canine ventricular tissues [139], but to abbreviation of ventricular APD in species that normally exhibit brief action potentials (e.g., mouse and rat) [140]. Pathophysiologic conditions (e.g., ischemia, metabolic inhibition) and some pharmacologic interventions (e.g., $I_{Na}$ or $I_{K}$ blockers or ATP-sensitive current ($I_{K,ATP}$, $I_{K_2}$ or $I_{K_3}$ activators) can lead to marked abbreviation of APD in canine and feline [141] ventricular cells where $I_n$ is prominent. Under these conditions, canine ventricular epicardium exhibits an all-or-none repolarization as a result of the shift in the balance of currents flowing at the end of phase 1 of the action potential. All-or-none repolarization
of the action potential occurs when phase 1 reaches approximately –30 mV. This leads to loss of the action potential dome as the outward currents overwhelm the inward currents. Loss of the dome generally occurs at some epicardial sites but not others, resulting in the development of a marked dispersion of repolarization within the epicardium as well as transmurally, between epicardium and endocardium. Propagation of the action potential dome from the epicardial site at which it is maintained to sites at which it is abolished can cause local re-excitation of the preparation. This mechanism, termed phase 2 reentry, produces extrasystolic beats capable of initiating circus movement reentry [142]. Phase 2 reentry has been shown to occur when right ventricular epicardium is exposed to: 1) K+ channel openers such as pinacidil [143]; 2) sodium channel blockers such as flecainide [144]; 3) increased [Ca2+] [115]; 4) calcium channel blockers such as verapamil; 5) metabolic inhibition [145]; and 6) simulated ischemia [142].

Table 3 provides a list of the drugs thus far identified as capable of inducing a Brugada ECG phenotype. Antiarrhythmic agents exhibiting potent use-dependent Ina block have been shown to induce or unmask the Brugada ECG. These agents include ajmaline, flecainide, procainamide, disopyramide, propafenone and pilsicainide [146–148]. Antiarrhythmics and antipsychotic agents have also been reported to induce the Brugada pattern. A study of 98 patients experiencing an overdose of tricyclic antidepressants reported that 15 of them displayed an ECG consistent with BrS [149]. The overall mortality was 3% among all patients but 6.7% among patients that displayed a Brugada phenotype. Rouleau et al. [150] described 3 cases of psychotropic drug-induced BrS ECG, occurring during concomitant administration of amitryptiline and a phenothiazine (case 1), overdose of fluoxetine (case 2), and co-administration of trifluoperazine and loxapine (case 3). Babaliaros and Hurst [151] described a Brugada pattern in patients receiving increasing doses of imipramine. Akhtar and Goldschlager [152] recently reported a case of BrS following overdose of desipramine and clonazepam (Fig. 3). Chow et al. [153] reported a similar case following desipramine. Bolognesi et al. [154] described a Brugada ECG pattern following overdose of amitryptiline and with maprotiline. Two additional cases of BrS were reported following overdose with nortryptiline [155, 156] or lithium [157]. The available data suggest most cases of antidepressant and antipsychotic-induced BrS phenotype occurs as a consequence of drug overdose or drug combination.

Exaggerated or otherwise abnormal J waves have long been linked to idiopathic ventricular fibrillation as well as to the BrS [116, 158–162]. The Brugada syndrome is characterized by exaggerated J wave that manifests as an ST segment elevation in the right precordial leads [116]. A number of studies have highlighted the similarities between the conditions that predispose to phase 2 reentry and those that attend the appearance of the BrS. Loss of the action potential dome in epicardium, but not endocardium generates a transmural current that
manifests on the ECG as an ST segment elevation, similar to that encountered in patients with the BrS [99, 145, 163]. Evidence in support of a phase 2 reentrant mechanism in humans was recently provided by Thomsen et al. [164, 165].

Parasympathetic agonists like acetylcholine facilitate loss of the action potential dome [166] by suppressing Ica and/or augmenting potassium current. Beta-adrenergic agonists restore the dome by augmenting Ina. Agents that inhibit the sodium channel current facilitate loss of the canine right ventricular action potential dome via a negative shift in the voltage at which phase 1 begins [144, 167]. These findings are consistent with accentuation of ST segment elevation in patients with the BrS following vagal maneuvers or Class I antiarrhythmic agents as well as normalization of the ST segment elevation following β adrenergic agents and phosphodiesterase III inhibitors [99, 168, 169]. Loss of the action potential dome is more readily induced in right vs. left canine ventricular epicardium [10, 145, 163] because of the more prominent Ina-mediated phase 1 in action potentials in this region of the heart. As previously noted, this distinction is believed to be the basis for why the BrS is a right ventricular disease.

In the past, much of the focus was on the ability of a reduction in sodium channel current to unmask the BrS and create an arrhythmogenic substrate. A recent report shows that a combination of Ina and Ica block is more effective than Ina inhibition alone in precipitating the BrS in the arterially-perfused wedge preparation [170].

The ST segment elevation associated with the BrS has been attributed to: 1) conduction delay in the right ventricular epicardial free wall in the region of the outflow tract (RVOT) [171] and/or 2) accentuation of the right ventricular epicardial action potential that may lead to loss of the action potential dome [172]. The cellular mechanisms thought to be responsible for the development of the Brugada phenotype via hypothesis 2 is schematically illustrated in Figure 4 [173, 174].

The ST segment is usually isoelectric because of the absence of transmural voltage gradients at the level of the action potential plateau (Fig. 4A). Accentuation of the right ventricular notch under pathophysiologic conditions leads to exaggeration of transmural voltage gradients and thus to accentuation of the J wave or to J point elevation. When epicardial repolarization precedes repolarization of the cells in the M and endocardial regions the T wave remains positive. This results in a saddleback configuration of the repolarization waves (Fig. 4B).

Further accentuation of the notch may be accompanied by a prolongation of the epicardial action potential such that the direction of repolarization across the right ventricular wall and transmural voltage gradients are reversed, leading to the development of a coved-type ST segment elevation and inversion of the T wave (Fig. 4C), typically observed in the ECG of Brugada patients. A delay in epicardial activation may also contribute to inversion of the T wave. The downsloping ST segment elevation observed in the experimental wedge models often appears as an R', suggesting that the appearance of a right bundle branch block (RBBB) morphology in Brugada patients may be due at least in part to early repolarization of right ventricular (RV) epicardium, rather than major impulse conduction block in the right bundle.

Gussak et al. [175] pointed out that a majority of RBBB-like morphologies encountered in cases of BrS do not fit the criteria for RBBB. Moreover, attempts by Miyazaki et al. [168] to record delayed activation of the RV in Brugada patients met with failure.

It is important to point out that although the typical Brugada morphology is present in Figure 4B and C, an arrhythmogenic substrate is absent. The arrhythmogenic substrate is thought to develop when a further shift in the balance of current leads to loss of the action potential dome at some epicardial sites but not others (Fig. 4D). Loss of the action potential dome in epicardium but not endocardium results in the development of a marked transmural dispersion of repolarization and refractoriness, responsible for the development of a vulnerable window during which a premature impulse or extrasystole can induce a reentrant arrhythmia. Conduction of the action potential dome from sites at which it is maintained to sites at which it is lost causes local re-excitation via a phase 2 reentry mechanism, leading to the development of a very closely-coupled extrasystole, which captures the vulnerable window across the wall, thus triggering a circus movement reentry in the form of VT/VF (Fig. 4E) [142, 176]. The phase 2 reentrant beat fuses with the T wave of the basic response, thus accentuating the negative T wave. This morphology is often observed in the clinic preceding the onset of polymorphic VT.

Studies involving the arterially-perfused right ventricular wedge preparation provide evidence in support of these hypotheses [176]. Aiba et al. [177] used a high resolution optical mapping system that allows simultaneous recording of transmembrane action potentials from 256 sites along the transmural surface of the arterially-perfused canine right-ventricular
wedge preparation to demonstrate that a steep repolarization gradient between the region at which the dome is lost and the region at which it is maintained is essential for the development of a closely coupled phase 2 reentrant extrasystole. This study also showed that reentry initially rotates in the epicardium and gradually shifts to a transmural orientation, responsible for nonsustained polymorphic VT or VF.

Kurita et al. placed monophasic action potential (MAP) electrodes on the epicardial and endocardial surfaces of the RVOT in patients with the BrS and demonstrated an accentuated notch in the epicardial response, thus providing support for this mechanism in humans [178, 179].

Thus, accentuation of the right ventricular epicardial action potential notch underlies the ST segment elevation. Eventual loss of the dome of the right ventricular epicardial action potential further exaggerates ST segment elevation. A vulnerable window is created both within epicardium, as well as transmurally, which serves as the substrate for the development of reentry (Fig. 5).

Phase 2 reentry provides the extrasystole that serves as the trigger that precipitates episodes of ventricular tachycardia and fibrillation in the BrS. Evidence in support of this hypothesis was recently provided in an arterially-perfused canine right ventricular experimental model of the BrS [176]. The VT and VF generated in these preparations is usually polymorphic, resembling a rapid form of torsade de pointes. This activity is likely related to the migrating spiral wave shown to generate a pattern resembling a polymorphic VT [180, 181].

**Role of TDR in drug-induced arrhythmogenesis**

In the acquired long QT syndrome, QT interval increases as a function of drug concentration, whereas in BrS it remains largely unchanged. What these two drug-induced syndromes have in common is an amplification of spatial dispersion of repolarization, TDR in particular, which results in the development of TdP when dispersion reaches the threshold for reentry.

**Genetic predisposition**

The degree to which a genetic predisposition contributes to the clinical manifestation of drug-
-induced arrhythmogenesis is not well defined. Available data suggest that up to 10–15% percent of individuals who develop TdP following exposure to QT-prolonging drugs possess mutations associated with the LQTS and may be considered to have a subclinical form of the congenital syndrome [182–186].

Abbot et al. [187] were among the first to show that a polymorphism (i.e., a genetic variation that is present in greater than 1% of the population) in an ion channel gene is associated with a predisposition to drug-induced TdP. They identified a polymorphism (T8A) of the KCNE2 gene encoding for MiRP, a beta subunit of the IKr channel, that is present in 1.6% of the population and is associated with TdP related to quinidine and to sulfamethoxazole/trimethoprim administration. This finding suggests that common genetic variations may increase the risk for development of drug related arrhythmias. Yang et al. [185] showed that DNA variants in the coding regions of congenital long-QT disease genes predisposing to acquired LQTS can be identified in approximately 10% to 15% of affected subjects, predominantly in genes encoding ancillary subunits, providing further support for the hypothesis that subclinical mutations and polymorphisms may predispose to drug-induced TdP. Splawski et al. [188] further advanced this concept by identifying a heterozygous polymorphism involving substitution of serine with tyrosine in codon 1103 (S1103Y) in the sodium channel gene SCN5A (S1102Y in the shorter splice variant of SCN5A) among Africans and African Americans that increases the risk for acquired TdP. The polymorphism was present in 57% of 23 patients with pro-arrhythmic episodes, but in only 13% of controls. These findings suggest that carriers of such polymorphisms can be identified and excluded from treatment with drugs that are associated with a risk of proarhythmia. It is conceivable that such testing could be applied widely since accurate results could be made available rapidly at relatively low cost.

Another common polymorphism that has been associated with acquired forms of LQTS and TdP is K897T in KCNH2 [189]. Most functional expression studies have reported that K897T reduces Ikr, [190–192] although one study has reported an increase in HERG current [193].

The action of antidepressants to precipitate the BrS may also have a genetic disposition. For example, the SCN5A promoter haplotype (so-called Hap B) has been shown to be associated with longer PR and QRS intervals as well as a more exaggerated response to sodium channel blockers [135].

Genetic defects can also contribute to drug-induced channelopathies by influencing the metabolism of drugs. In the case of relatively pure Ikr blockers, there is a clear relationship between plasma levels of drug and the incidence of TdP. Genetic variants of the genes encoding for enzymes responsible for drug metabolism could alter pharmacokinetics so as to cause wide fluctuations in plasma levels, thus exerting a significant proarhythmic influence [194, 195]. For example, in the case of cytochrome CYP2D6, which is involved in the metabolism of some QT prolonging drugs (terodiline, thioridazine), multiple polymorphisms have been reported that reduce or eliminate its function; 5–10% of Caucasians and African-Americans lack a functional CYP2D6. Numerous proteins, including drug transport molecules and other drug metabolizing enzymes, are involved in drug absorption, distribution, and elimination and genetic variants of each of these has the potential to modulate drug concentrations and effects. Multiple substrates and inhibitors of the cytochrome P450 enzymes have been identified. A comprehensive database can be found at http://medicine.iupui.edu/flockhart/.
