Abstract

Background: Coronary artery disease (CAD) affects millions of people and can result in myocardial infarction (MI). Previously, mast cells (MC) have been extensively investigated in the context of hyper-sensitivity, however as regulators of the local inflammatory response they can potentially contribute to CAD and/or its progression. The aim of the study was to assess if serum concentration of MC proteases: carboxypeptidase A3, cathepsin G and chymase 1 is associated with the extension of CAD and MI.

Methods: The 44 patients with angiographically confirmed CAD (23 subjects with non-ST-segment elevation MI [NSTEMI] and 21 with stable CAD) were analyzed. Clinical data were obtained as well as serum concentrations of carboxypeptidase A3, cathepsin G and chymase 1 were also measured.

Results: Patients with single vessel CAD had higher serum concentration of carboxypeptidase than those with more advanced CAD (3838.6 ± 1083.1 pg/mL vs. 2715.6 ± 442.5 pg/mL; p = 0.02). There were no significant differences in levels of any protease between patients with stable CAD and those with NSTEMI. Patients with hypertension had ≈2-fold lower serum levels of cathepsin G than normotensive individuals (4.6 ± 0.9 pg/mL vs. 9.4 ± 5.8 pg/mL; p = 0.001). Cathepsin G levels were also decreased in sera of the current smokers as compared with non-smokers (3.1 ± 1.2 ng/mL vs. 5.8 ± 1.2 ng/mL, p = 0.02).

Conclusions: Decreased serum level of carboxypeptidase is a hallmark of more advanced CAD. Lower serum levels of carboxypeptidase A3 and cathepsin G are associated with risk factors of blood vessel damage suggesting a protective role of these enzymes in CAD. (Cardiol J XXXX; XX, X: xx–xx)

Key words: mast cells, carboxypeptidase A3, cathepsin G, chymase 1, coronary artery disease
Introduction

Chronic inflammation plays an important role in the pathogenesis of coronary artery disease (CAD) and acute myocardial infarction (AMI). The link between mast cell (MC) proteases and a local inflammation process is an attractive research area. After activation, MC releases a wide range of proteases that have a potential pro- or anti-inflammatory effect [1–3]. The major MC proteases include tryptase, chymase 1, carboxypeptidase A3 and cathepsin G.

In previously published work, it was shown that tryptase and endothelin-1 released from activated MC are elevated in patients with an AMI [4]. Therefore, in the current study the aim was to analyze if other MC proteases chymase 1, carboxypeptidase A3 and cathepsin G play also have a role in CAD and AMI.

Chymase 1 is a serine protease stored in MC. It is released after stimulation during an inflammatory or ischemic injury that is known to be a hallmark of AMI. The protein release is associated with activation of matrix metalloproteinase-9, which was shown to increase infarct size in an experimental model [5]. Oyamada et al. [6] have shown, that chymase 1 inhibition results in myocardial protection and attenuates fibrosis after AMI. In addition, chymase plays a crucial role in transformation of angiotensin I to angiotensin II independent from angiotensin converting enzyme [7].

Cathepsin G is a serine protease also synthesized and stored in MC. However, MC are not the only source of the enzyme, it is also released from activated neutrophils and macrophages [8–10]. Despite that cathepsin G may promote early atherogenesis as it is an elastase [11] and collagenase activator [12]. Wang et al. [13] suggested that cathepsin G promotes early atherogenesis through its elastinolytic activity, but at the same time suppresses late progression of atherosclerosis. In their study, patients with atherosclerosis had significantly reduced plasma levels of cathepsin G that were in negative correlation with total cholesterol and low density lipoprotein (LDL), but not high density lipoprotein (HDL) or triglycerides, suggesting a role of cathepsin G in degradation of LDL without affecting HDL or triglycerides [13].

A carboxypeptidase A3 (CPA3) is a zinc metalloprotease that is released from MCs and basophils as well. This enzyme degrades proteins and peptides, including the apolipoprotein B; a component of LDL particles [14]. Upon MC activation and degranulation, CPA3 with the chymases and tryptases interacts with heparin proteoglycans [15]. It was shown to play a role in the inactivation of endothelin [16, 17] and degradation of angiotensin II [18], which suggests its antihypertensive activity.

The aim of the study was to check if a concentration of MC derived proteases is elevated in sera of patients with different extensions of CAD, and thus to assess the role of MC in its pathogenesis.

Methods

This was a prospective and single-center study. The study was conducted according to the Declaration of Helsinki and the protocol was reviewed and approved by the local ethics committee. All patients gave written informed consent.

Patients

Between November 2012 and May 2013, 44 consecutive patients were prospectively screened who underwent diagnostic coronary angiography because of non-ST-segment elevation myocardial infarction (NSTEMI) or stable angina with a positive stress test. All the procedures were performed at the Department of Invasive Cardiology, Pomeranian Cardiology Centres, Wejherowo, Poland. Patients with renal failure, malignancy, and acute or chronic inflammatory disease were excluded from the study. Finally, 44 patients (23 NSTEMI and 21 with stable angina) were included. Complete demographic and clinical data were obtained. Accordingly to the extension of CAD, patients were divided into two groups: subjects with one vessel CAD and those with two or three vessel CAD.

Blood sampling and laboratory tests

The blood samples were obtained after puncture of a radial or a femoral artery and they were drawn from the vascular sheath during a coronary angiography.

Then, blood samples were centrifuged at 1000 × g for 15 min to obtain serum. Subsequently, standard clinical parameters were measured and the remaining serum was apportioned into 0.5 mL aliquots, and stored at –80°C until analysis of CPA3, cathepsin G and chymase 1.

Measurement of CPA3, cathepsin G and chymase 1

Carboxypeptidase A3, cathepsin G and chymase 1 concentrations were measured with ELISA (Cloud-Clone Corp., Houston, TX, USA) according to manufacturer instructions. The lower limit of
detection of CPA3, cathepsin G and chymase 1 was < 3.0 pg/mL, < 0.065 ng/mL and < 13.5 pg/mL, respectively. Protein concentration was measured spectrophotometrically (Perkin Elmer VICTOR X4) at a wavelength of 450 ± 10 nm and was determined by comparing the O.D. of samples to a standard curve.

Statistical analysis
The results are expressed as mean ± standard deviation. Comparisons between groups were performed using the t-Student test for continuous variables and χ² test for categorical variables. Wizard Statistics 1.8.16 software was used for analysis, p-value < 0.05 was considered statistically significant.
Results

The demographic and biochemical data of 44 patients with significant CAD are presented in Table 1. Patients with more advanced CAD had more often had a history of previous myocardial infarction (MI). The major clinical and biochemical data of 23 NSTEMI patients were compared to subjects with stable CAD are listed in Table 2. Patients with stable CAD had more often had a history of MI in the past and presented more often with three vessel CAD compared to NSTEMI patients. On the other hand, subjects with NSTEMI had significantly higher levels of C-reactive protein and lower glomerular filtration rate.

Patients with one vessel CAD presented a significantly higher level of carboxypeptidase A3 than those with more advanced CAD. Neither the cathepsin G nor chymase differed between the two groups (Fig. 1).

Significantly lower levels of cathepsin G were observed among patients with CAD and hyperten-
sion as compared with normotensive CAD subjects (Fig. 2). Lower serum concentrations of cathepsin G in individuals with CAD were also associated with smoking (Fig. 3).

There were no statistically significant differences in levels of any protease between patients with stable CAD and those with NSTEMI (Fig. 4).

Discussion

Mast cells have been extensively investigated in the context of hypersensitivity [19] and little is known about their influence on the human body apart from allergic inflammation. However, in the present study it was shown that serum concentration of MC derived enzyme CPA3 was decreased in patients with more advanced CAD. In addition, higher levels of cathepsin G were found in normotensive CAD patients and in those who were non-smokers. This data has shed new light on MC and the role of their activation in cardiovascular diseases.

Previously, Xiang et al. [20] reported increased chymase concentration in patients with MI. How-

Figure 3. The differences in serum concentrations of carboxypeptidase A3 (pg/mL), chymase 1 (pg/mL) and cathepsin G (ng/ml) among patients with coronary artery disease (CAD) according to their smoking status.

Figure 4. The differences in serum concentrations of carboxypeptidase A3 (pg/mL), chymase 1 (pg/mL) and cathepsin G (ng/ml) in patients with stable coronary artery disease (CAD) and non-ST-segment elevation myocardial infarction (NSTEMI); AMI — acute myocardial infarction.
ever, there is no data concerning a possible association of carboxypeptidase and presence of CAD. In the current study, significantly higher levels of CPA3 were observed in patients with angiographically confirmed single vessel CAD as compared with subjects with advanced two or three vessel disease.

Carboxypeptidase A3 and chymase 1 play a key role in the formation as well as degradation of angiotensin II [18]. Whereas chymase is the main tissue convertor of angiotensin I to angiotensin II, CPA3 creates peptides Ang-(1–9) and Ang-(1–7) that antagonize angiotensin II [18]. The peptide angiotensin II is not only a strong vasoconstrictor, but it also can promote atherosclerosis via several biologic activities such as: an increased expression of adhesion molecules on endothelial cells, activation of macrophages and upregulation of matrix metalloproteinases and proinflammatory cytokines [21, 22]. Therefore, as an indirect antagonist of angiotensin II, CPA3 exerts a protective effect in CAD. CPA3 was also found to degrade another vasoconstrictor — endothelin-1 and was found to play a cardioprotective effect during ischemia-reperfusion injury [23]. In addition, the present study revealed that lower serum concentration of the peptide was characteristic for patients with more advanced CAD and also for those who were active smokers. As smoking is one of the most widely known risk factors of cardiovascular diseases [24], this data suggests that one of the mechanisms of the deleterious impact of smoking on blood vessels might be an inhibitor of CPA3 production. Thus, all these data together confirms a protective effect of this enzyme in CAD.

When NSTEMI patients were compared with those having stable CAD, nosignificant differences were found in the levels of any of the proteases studied. Previously Xiang et al. [20] reported that serum chymase levels were higher in patients with AMI compared to subjects with stable CAD, however this difference was not statistically significant [20]. The lack of significant differences in serum levels of chymase between patients with MI and stable CAD in the cited study and chymase and carboxypeptidase of the present research may reflect the fact that an underlying mechanism of angiotensin II regulation influences chronic atherosclerosis rather than a formation of unstable coronary plaque and consequently AMI.

The concentration of cathepsin G was significantly lower in current smokers and hypertensive patients than in non-smokers and normotensive individuals, respectively. Wang et al. [13] has shown, that cathepsin G promoted early atherogenesis through its elastinolytic activity, but on the other hand it suppressed late progression of atherosclerosis by degrading LDL. In their study patients with CAD were characterized with significantly lower levels of cathepsin G and higher levels of LDL, than individuals without CAD [13]. In the present study, decreased serum concentration of cathepsin G in CAD patients was associated with tabacco smoking or hypertension. Cathepsin G was found to exert an anti-inflammatory effect by reducing biological activity of inflammatory cytokines [25]. As both hypertension and smoking are associated with inflammation and increased production of pro-inflammatory cytokines [26], lower levels of protease in these patients may reflect an exhaustion of its production in chronic inflammation.

Conclusions

1. Decreased serum concentration of CPA3 is a hallmark of more advanced CAD.
2. Lower serum levels of CPA3 and cathepsin G are associated with risk factors of blood vessel damage suggesting a protective role of these enzymes in CAD.
