Abstract

Background: The prevalence of diabetes has increased significantly in well-developed countries during the last decade and it continues to grow. Diabetes increases the risk of restenosis in patients treated percutaneously for peripheral artery disease. The present study sought to compare outcomes of atherectomy treatment in diabetic (DM) vs. non-diabetic (nDM) patients suffering from peripheral artery disease.

Method: Between 2008 and 2012, 204 revascularization atherectomy procedures were performed on arteries of the lower extremities. The endpoints included target lesion revascularization (TLR), amputation and death. The type of atherectomy (excisional-soft plaque, orbital-calcified plaque, with active aspiration — with a thrombus) was left to operator discretion.
Results: This study contains 132 DM (66% male, age 68 ± 11.2 years) and 72 nDM (63% male, age 75 ± 11.3 years) subjects. DM were younger but had a higher prevalence of coronary artery disease (DM: 91% vs. nDM: 62%, p < 0.0001) and end-stage renal disease (DM: 22% vs. nDM: 2.5%, p < 0.0001). There were no differences in critical limb ischemia between the groups (DM: 21% vs. nDM: 12%, p = 0.13). Mean time of follow-up was 384 and 411 days in DM and nDM, respectively (p = 0.43). There were no significant differences in TLR (DM: 15.2% vs. nDM: 22.2%, p = 0.249), amputations (DM: 3.0% vs. nDM: 1.5%, p = NS) or death rates (DM: 2.2% vs. nDM: 2.7%, p = NS). Kaplan-Mayer analysis showed no significant differences between the groups in the time to TLR, amputation or death.

Conclusions: Plaque modification with adjusted atherectomy appears to have similar outcomes in diabetic as well as in non-diabetic patients. Nonetheless, a randomized study would be warranted to confirm the findings of the current study.

Key words: atherectomy, diabetes mellitus, peripheral artery disease, critical limb ischemia, claudication, below the knee, above the knee

INTRODUCTION
Diabetes mellitus (DM) has a pandemic status in well-developed countries. It is projected that DM will have a prevalence of 552 million worldwide by 2030 [1]. The strongest risk factors for peripheral artery disease (PAD) are DM and smoking [2]. Whereas the ratio of smokers is falling, the DM prevalence continues to increase. The symptomatic PAD is observed in 21% of patients with DM [3]. Moreover, DM is also an independent risk factor for chronic kidney disease which significantly increases the chance of PAD [4]. Over the years multiple therapies for PAD have emerged, including pharmacological regimens, endovascular and open surgery, drug-coated balloons (DCB), and stem cell therapy [5]. Nevertheless, revascularization of lower limb arteries in patients with DM brings disappointing long-term outcomes in comparison to the non-diabetic population [6, 7]. This could be caused by the fact that diabetic lesions in diabetic patients occur over a wider area of the vasculature, including small-diameter vessels [8]. As a result, the atherectomy type chosen based on the plaque morphology and vessel diameter may improve long-term outcomes [9].

The long-term outcomes of endovascular revascularization of lower limb arteries using
Atherectomy in diabetic patients remains unclear. Therefore, the aim of this study is to compare long-term outcomes after endovascular revascularization of lower limb arteries with atherectomy in diabetic (DM) and non-diabetic (nDM) patients.

**METHOD**

**Subjects**

This study is based on a retrospective study of 203 consecutive patients with symptomatic PAD who underwent endovascular revascularization with atherectomy between 2008 and 2012 at San Antonio Endovascular and Heart Institute. 132 patients were diabetic, whereas 72 were non-diabetic.

Adult patients (> 18 years old) with both intermittent claudication (Rutherford 3) and critical limb ischemia (CLI; Rutherford 4–6) were included provided they had at least 1 lesion with > 70% diameter stenosis confirmed on live quantitative vessel angiography in a lower extremity artery. Patients with in-stent restenosis and diabetes type 1 were excluded.

**Procedural characteristic and pharmacological regimen**

Directional (Silver Hawk™, Medtronic), orbital (Diamondback 360°, CSI 360°) and directional with suction (Jetstream™, Boston Scientific) atherectomy (AT) devices were applied in this study. The type of AT was left to operator discretion, nonetheless directional AT was performed in soft and mixed plaques; orbital AT was applied when a lesion appeared to be calcified; and directional AT with suction was performed when thrombus was suspected. Orbital AT was always followed by the low-pressure balloon post-dilatation; and after directional AT, percutaneous transluminal angioplasty (PTA) was performed if residual stenosis was > 30%. The Distal protection system was not used for any patient. Angiographic success was defined as post-procedural Thrombolysis in Myocardial Infarction (TIMI) 3 flow, no dissection or residual stenosis < 30%. If angiographic success was not achieved, bail-out stenting was performed. Acetylsalicylic acid (81 mg/day) was continued indefinitely whereas clopidogrel (75 mg/day) was advised to be continued for 12 months after the procedure together with atorvastatin, at the maximum tolerable dose, usually 40 mg daily.
Atherectomy devices

The Silver Hawk plaque excision system (Medtronic) is a forward cutting directional AT device. The device consists of a rotating blade inside a tubular housing with a collection space in the nose cone. The device enables the performance of AT in vessels with a diameter of 1.5–7 mm.

Diamondback 360° (CSI360°) is an orbital AT system tipped with an eccentric, diamond-coated crown. The crown rpm can vary from 60,000 to 200,000. The crown may be advanced forward and backward when it is intra-arterial. The needed diameter is achieved by increasing the speed of rotation. Faster speeds result in an increased centrifugal force, yielding a larger orbit, and this device is recommended for calcified lesions. Usually, orbital AT is performed before stenting/balloon angioplasty.

The Pathway Jetstream PV Atherectomy System (Boston Scientific) is a rotational AT device with a front-cutting tip that spins at 60–70,000 rpm. Jetstream® expandable catheters have a catheter tip that remains at a diameter of 2.1–2.4 mm when rotating clockwise and 2.4–3.4 mm when rotating counterclockwise. For below the knee interventions this device is available in a fixed size: 1.6 mm and 1.85 mm. This is the only AT device on the market with active aspiration. The derbies as well as thrombus are collected in a bag located on the console device, outside the body.

Study endpoints and definitions

Because of the observational nature of this study, no preliminary hypothesis was generated. Target lesion revascularization (TLR) was considered a primary endpoint and was defined as any symptom-driven revascularization within a previously treated segment. Unplanned amputation related to a previously treated vessel, death and a change in the Rutherford class were regarded as secondary endpoints. Furthermore, incidents of vessel perforation, dissection and distal embolization, and bailout stenting were collected.

Safety and ethics
This retrospective study was conducted in accordance with standard ethics guidelines. Endovascular procedures were carried out by experienced interventional cardiovascular teams in a high-volume center with a vascular surgery back up within 30 min of transportation.

Owing to the observational and retrospective nature of this study, neither patient consent nor ethics committee approval was required.

**Data collection and follow-up**

Clinical and procedural data were collected on case report forms generated by the hospital electronic system, containing all patient hospitalization and discharge information. This system is audited for institutional quality assurance by private insurance companies and the state health fund.

Long-term follow-up data were collected during ambulatory check-ups or over the phone. The follow-up office visits were usually scheduled every 3–5 months. Some patients had phone consultations due to a lack of symptoms, and office-based follow-ups were scheduled on a further date. All outcomes of interest were confirmed using hospital discharge charts. Three patients met exclusion criteria for in-stent restenosis and 3 were lost to follow-up.

**Statistical analysis**

Continuous variables are presented as mean ± standard deviation or median (interquartile range [IQR]). Data were compared using the t-test for parametric or Mann-Whitney U-test for non-parametric continuous variables. Categorical variables are reported as frequencies (percentages) and were compared using the $\chi^2$ or Fisher exact test, as appropriate. Survival curves were constructed using the Kaplan-Meier estimates and were compared with the log-rank test. All reported p-values are two-tailed, and $p < 0.05$ was considered as significant. GraphPad 6 Prism was used for statistical analysis.

**RESULTS**
The method of diabetes control was primarily oral agents (56.3%, n = 73) followed by insulin injections (36.6%, n = 48) or a combination of both (8.3%, n = 11). Patients in the diabetic cohort were significantly younger but had considerably more risk factors including off-range body mass index (BMI), coronary artery disease, artery bypass grafting (CABG), percutaneous coronary interventions (PCI) and dialysis-dependent renal insufficiency (Table 1). The mean time of follow-up was 384 and 411 days in DM and nDM, respectively (p = 0.43).

Lesion characteristics were similar in DM (n = 198) and nDM (n = 106) patients with a mean number of lesions per patient equaling 1.5 in both groups. Lesion location was primarily superficial femoral artery in nDM (33%, n = 38), whereas in the DM cohort anterior tibial artery was most frequently revascularized (29.7%, n = 59). There were no significant differences in target lesions between the groups. Furthermore, there were no differences between the groups in terms of lesion morphology in the TransAtlantic Inter-Society Consensus (TASC) and the number of total chronic occlusion. There were no significant differences between the groups in the choice of atherectomy, except for JetStream in favor in the case of the nDM group (Table 2).

The number of periprocedural complications was similar between the groups. The detailed periprocedural outcomes are shown in Table 3.

At follow-up there were no differences between the groups in TLR after 6 months (DM: 7.5% vs. nDM 2.8%, p = 0.224), 12 months (DM: 13.6% vs. nDM 20.8%, p = 0.232) or 24 months (DM: 15.2% vs. nDM 22.2%, p = 0.249) as shown in Figure 1. The amputation and death ratios were comparable between the groups (DM: 3% vs. nDM 1.5%, p = NS) and (DM: 2.2% vs. nDM 2.7%, p = NS) respectively, as also shown in Figure 1. In the Kaplan-Mayer analysis, there were no differences in TLR-free survival, amputation free survival and survival (p = 0.27, hazard ratio [HR] 0.714, 95% confidence interval [CI] 0.371–1.314; p = 0.81, HR 0.8, 95% CI 0.127–5.041; p = 0.557, HR 4.542, 95% CI 0.562–36.69) respectively, as shown in Figure 2. Moreover, there were no differences in the TLR between the groups depending on the artery and type of atherectomy device.

There were no significant differences in the Rutheford class between the groups during follow-up. However, there was a significant drop in the Rutherford class between groups before and after revascularization (< 0.0001) as shown in Figure 3.
DISCUSSION

The current study presents a direct observational comparison of patients revascularized with atherectomy chosen based on plaque morphology in DM and nDM patients. According to available research, the present study, for the first-time, describes a direct comparison of long-term outcomes for different types atherectomies in diabetics versus non-diabetics in claudicates as well as in critical limb ischemia patients. In this study, despite some discrepancies in patient baseline characteristics in favor of the nDM group, there were no differences in periprocedural complications, target lesion revascularization, amputation or death. It should be noted that the DM group consisted of high-risk patients for major cardiovascular adverse events due to numerous risk factors like end-stage renal disease, advanced coronary artery disease and obesity. Moreover, lesion characteristics are comparable between the groups. The difficulties treating PAD in diabetic patients have been driven by numerous factors including diffuse atherosclerosis causing longer lesions with smaller diameter lumen, more calcifications and greater plaque burden [10]. Furthermore, DM is associated with a more severe below-the-knee PAD, whereas risk factors, such as smoking, are associated with more proximal lesions [8].

There is very little data comparing long-term outcomes after treatment in patients with DM vs. nDM in PAD. A sub-analysis of Definitive Le comparing revascularization with SliverHawk/TurboHawk in diabetics and non-diabetics showed that directional atherectomy is equally effective in both groups of patients [11]. The ratio of target lesion revascularization was similar between the groups at 12-month follow-up and equaled 83.8% and 87.5% for diabetics and non-diabetics respectively. Just as in our database, the revascularization in Definitive Le was more frequent in case of below the knee procedures and the characteristics of demographics were similar. Nevertheless, in the Definitive Le study patients with critical limb ischemia were excluded. Lee et al. [6] compared the efficiency of plain old balloon angioplasty (POBA) in DM and nDM patients [6]. This study with a 2-year follow-up showed that POBA is less effective in diabetic patients, with a higher rate of restenosis and amputations. On the other hand, the drug eluting balloon (DEB) in the small study showed better outcomes in comparison to POBA in below-the-knee lesions at 3-month follow-up. Nevertheless, no benefits of DEB after 12 months were reported [12]. While comparing the stent technology, the Zilver PTX study reported that DM and nDM cohorts in their study had similar outcomes using the paclitaxel eluting stent [13]. Nonetheless, only superficial femoral
artery was included as the target vessel. Darling et al. [7] published a direct comparison of diabetics and non-diabetics treated with POBA or bypass surgery in CLI patients. According to observations of this group, diabetics manifested an increased risk of long-term mortality, incomplete wound healing, a major amputation and restenosis, especially after POBA in comparison to non-diabetics. Furthermore, Dick et al. [14] published a study with results similar to the study mentioned earlier.

There is an interesting technology that may be combined with atherectomy in PAD and it is the local drug delivery after revascularization. Early reports on the combination of plaque modification with atherectomy and subsequent DEB seem to be promising [15, 16]. Novel technologies, including local drug delivery nano-technology, may soon become available for follow-up treatment of plaque modifications after atherectomy [17].

All patients in this study were also treated pharmacologically to reduce any major cardiovascular adverse events. Despite encouraging data on including cilostazol in the treatment after stenting of femoropopliteal region [18], almost all the present patients were on dual antiplatelet therapy (DAPT) consisting of clopidogrel (75 mg) and acetylsalicylic acid (81 mg) once a day. Dual antiplatelet therapy was prescribed due to the fact that after AT, the intima-media could be exposed to blood flow, significantly increasing the risk of acute or subacute thrombosis [19].

To summarize, this study shows that the outcomes of atherectomy in PAD are similar in DM patients as compared to nDM patients. The large minimal lumen diameter obtained during atherectomy may play a crucial role in this phenomenon, which translates into a lower TLR ratio at follow-up in diabetics as well as non-diabetics.

**Limitations of the study**

The main drawbacks of this analysis are those inherent to any single-center, observational study [20], along with differences in baseline patient characteristics. Nevertheless, the differences arise from the character of DM and nDM patients. The exact data on very long below the knee chronic total occlusion are unavailable. The ABI, USG, Doppler and toe pressure were not performed on each visit, making this data unsuitable for statistical analysis. This study is hypothesis-generating only.
CONCLUSIONS

In this hypothesis-generating study of patients with lower extremity PAD, plaque modifications with adjusted atherectomies appear to have similar outcomes in diabetic as well as in non-diabetic patients. Nevertheless, this should be confirmed in further controlled randomized trials.
