Abstract
The definition of heart failure with preserved ejection fraction (HFpEF) has evolved from a clinically based “diagnosis of exclusion” to definitions focused on objective evidence of diastolic dysfunction and/or elevated left ventricular filling pressures. Despite advances in our understanding of HFpEF pathophysiology and the development of more sophisticated imaging modalities, the diagnosis of HFpEF remains challenging, especially in the chronic setting, given that symptoms are provoked by exertion and diagnostic evaluation is largely conducted at rest. Invasive hemodynamic study, and in particular — invasive exercise testing, is considered the reference method for HFpEF diagnosis. However, its use is limited as opposed to the high number of patients with suspected HFpEF. Thus, diagnostic criteria for HFpEF should be principally based on non-invasive measurements. As no single non-invasive variable can adequately corroborate or refute the diagnosis, different combinations of clinical, echocardiographic, and/or biochemical parameters have been introduced. Recent years have brought an abundance of HFpEF definitions. Here, we present and compare four of them: 1) the 2016 European Society of Cardiology criteria for HFpEF; 2) the 2016 echocardiographic algorithm for diagnosing diastolic dysfunction; 3) the 2018 evidence-based HFPEF score; and 4) the most recent, 2019 Heart Failure Association HFA-PEFF algorithm. These definitions vary in their approach to diagnosis, as well as sensitivity and specificity. Further studies to validate and compare the diagnostic accuracy of HFpEF definitions are warranted. Nevertheless, it seems that the best HFpEF definition would originate from a randomized clinical trial showing a favorable effect of an intervention on prognosis in HFpEF. (Cardiol J 2020; 27, 5: XXX–XXX)

Key words: diagnosis, diastolic function, E/e’ ratio, left atrial pressure, pulmonary capillary wedge pressure, natriuretic peptides, atrial fibrillation

Introduction
Heart failure with preserved ejection fraction (HFpEF) is one of the hot topics in modern cardiology. Entering “HFpEF”, “diastolic dysfunction”, or related terms into the MEDLINE (Medical Literature Analysis and Retrieval System Online) database results in over 12,000 citations, with a sharp increase in recent years. Despite well-defined demographic and clinical characteristics of HFpEF patients, as well as ongoing research and discussion on the essence of HFpEF, no uniform diagnostic criteria have been widely accepted, nor has any treatment been shown to improve prognosis [1]. Different definitions have been proposed by scientific societies or adopted in randomized clinical trials [1–11]. These definitions vary greatly in their approach to the diagnosis (clinically based vs. focused on objective evidence of diastolic dysfunction and/or elevated left ventricular [LV] filling pressure, with different combinations of parameters used in each definition), which may reflect limitations of our understanding of HFpEF pathophysiology but also different stages of HFpEF continuum with some definitions aiming at pre-clinical diastolic dysfunction, and some directed at clinically overt, advanced HFpEF (Fig. 1) [12, 13]. In everyday clinical practice, confirming or excluding HFpEF poses a considerable challenge with a potential for both overdiagnosis (mostly in primary care and in patients hospitalized for acute dyspnea) and underdiagnosis (especially in stable, uncongested, elderly patients with exertional symptoms) [14–24]. The abundance of HFpEF definitions might cause even more confusion among non-HF specialists. This article is an attempt to present the most up-to-date diagnostic criteria for chronic HFpEF, compare different definitions, and summarize their strengths and limitations.

Why is it difficult to establish diagnostic criteria for HFpEF?
As shown in Figure 1, different diagnostic parameters reflect different pathomechanisms and different stages of HFpEF. Furthermore, most parameters are not specific for HFpEF (Table 1 [4, 24–47]). Thus, no single variable, echocardiographic or biochemical, can adequately corroborate or refute the diagnosis [4, 5]. Moreover, for different parameters, no clear cut-off points can be defined because most of them are continuously distributed within a population and may vary depending on age, gender, body surface area, body mass index (BMI), heart rhythm, kidney function, and the presence of cardiac and extra-cardiac comorbidities [5]. Notably, choosing a “lower” value as a threshold for diagnosis would increase
Figure 1. Natural history of heart failure with preserved ejection fraction (HFpEF) with corresponding echocardiographic and invasively measured parameters. For clarity and to enhance educational value, separate pathophysiological stages have been distinguished with parameters allocated to each stage. In reality, these stages overlap and can change with time, volume status, and level of physical activity. The diagram does not include more sophisticated echocardiographic and invasives parameters, and it does not refer to all postulated pathomechanisms (such as microvascular inflammation or cardiometabolic abnormalities). Dotted line indicates parameters (measured during right heart catheterization [RHC]) that do not constitute criteria for the diagnosis of HFpEF by any definition. Stages of HF according to the American College of Cardiology Foundation (ACCF) and the American Heart Association (AHA) have been shown [2]; DD — diastolic dysfunction; dPAP — diastolic pulmonary artery pressure; GLS — global longitudinal strain; HF — heart failure; LAP — left atrial pressure; LAVI — left atrial volume index; LHC — left heart catheterization; LVEDP — left ventricular end-diastolic pressure; LVH — left ventricular hypertrophy; LVMI — left ventricular mass index; mPAP — mean pulmonary artery pressure; PCWP — pulmonary capillary wedge pressure; RV — right ventricle; RWT — relative wall thickness; sPAP — systolic pulmonary artery pressure; TAPSE — tricuspid annular plane systolic excursion; TRV — tricuspid regurgitation velocity.

| NPs       | The main trigger for release is increased LV end-diastolic wall stress | 1. In chronic HFpEF, NPs can be false negative:  
   — NPs are more sensitive for HFrEF: LV wall stress is proportional to LV radius and inversely proportional to LV wall thickness therefore NP levels are lower in HFpEF (hypertrophic, non-dilated LV) than in HFrEF (dilated LV); LV hypertrophy in HFpEF develops to reduce wall stress  
   — NPs are more sensitive for acute HF  
   — Obesity and female gender are associated with lower NPs  
2. NPs can be false positive in the absence of HFpEF:  
   — Older age, AF, kidney disease, valvular heart disease, pulmonary disease, and arterial pulmonary hypertension can result in elevated NPs  
3. NP levels can fluctuate in time |

</table>
| e’ (septal and lateral) | e’ reflects LV relaxation | — Measurement is angle-dependent  
— e’ decreases with age  
— e’ is unreliable in patients with mitral annular calcifications or prosthetic valves or rings  
— e’ can be influenced by regional wall motion abnormalities due to myocardial ischemia  
— TDI-derived parameters are much less preload-dependent than mitral inflow; however, e’ may increase with increased preload, mainly in subjects with normal LV function  
— in healthy subjects, e’ also increases with exercise-induced tachycardia |
| E and E/A | The E wave reflects LA-LV pressure gradient during early diastole, which depends on LA pressure and LV relaxation/LV stiffness | — E velocity is highly dependent on preload  
— tachycardia affects E velocity and can lead to fusion of E/A waves  
— E/A ratio not applicable in AF  
— E/A ratio is age-dependent  
— without additional variables normal and pseudonormal mitral inflow pattern are difficult to differentiate  
— increased E velocity and pseudonormal/restrictive mitral inflow pattern can be secondary to other causes, including in particular moderate-to-severe mitral regurgitation, volume overload (e.g. in kidney disease), constrictive pericarditis, etc. |
| E/e’ | The most appropriate echocardiographic parameter reflecting LV filling pressure:  
— E/e’ ≥ 15 has a high positive predictive value for elevated PCWP  
— E/e’ is less dependent on:  
• preload than E and e’ velocities  
• heart rate than E velocity  
• age than e’ velocity | — Correlation with invasive measurements is moderate with a “grey zone” for intermediate values of 9-14 |
| LAVI | Enlarged LA reflects longstanding elevation of LA pressure | — LA enlargement can be secondary to other causes, including in particular AF, mitral valve diseases, volume overload (e.g. in kidney disease), etc. (reduced specificity)  
— LA enlargement develops with time and can be absent at an early stage of HFpEF (reduced sensitivity) |
| TRV and sPAP | TRV is used for estimation of:  
— echocardiographic probability of pulmonary hypertension (as per 2015 ESC/ERS guidelines)  
— sPAP using simplified Bernoulli equation:  
\[ sPAP = 4 \times TRV^2 + \text{estimated right atrial pressure} \] | — Correlation with invasive measurements is moderate  
— TRV measurement may be difficult or impossible (e.g. in the case of absent or trivial tricuspid regurgitation or suboptimal acoustic window)  
— TRV and echocardiographically estimated sPAP increase with age  
— TRV is preload dependent  
— increase in TRV and sPAP can be secondary to other causes, including left heart disease other than HFpEF, pulmonary disease, pulmonary embolism and chronic thromboembolic pulmonary hypertension, pulmonary arterial hypertension, fluid overload, etc.  
— massive TR can result in low systolic RV-RA pressure gradient (low TRV) leading to underestimation of sPAP |
sensitivity at the expense of lower specificity, while setting a “higher” threshold would increase specificity at the expense of lower sensitivity. Thus, establishing cut-offs for echocardiographic variables and natriuretic peptides (NPs), though based on comparisons with invasive measurements, is inevitably arbitrary. The above considerations regarding adoption of cut-off points refer even to the “gold standard” of HFrEF diagnosis — heart catheterization [48, 49]. Invasive hemodynamic assessment is considered a reference investigation for diagnosing HFrEF [5, 12, 28]. However, it has limited availability compared to the large number of patients requiring diagnostic evaluation for this highly prevalent disease. Other limitations include unknown reproducibility and a questionable risk/benefit ratio of an invasive study in view of the lack of specific HFrEF treatment [12, 49]. Hence, ideally, in most patients, diagnosis should be made based on non-invasive testing. However, validation of NPs and echocardiographic indices of HFrEF shows their relatively poor correlation with invasive hemodynamic measurements [4, 24–30, 39, 44–46, 50]. Among different echocardiographic variables, the E/e’ ratio is considered the most appropriate for approximation of LV filling pressures, but its agreement with invasive measurements is only moderate [24–30]. Similarly, echocardiographic estimation of pulmonary artery pressure is not very accurate compared to right heart catheterization (RHC) [44–46]. This, again, explains the need for an algorithm including a combination of different non-invasive variables rather than a single parameter to diagnose HFrEF.

Another problem is that NP concentrations as well as echocardiographic indices of diastolic function and left atrial (LA) pressure can change in time, and therefore a single measurement of a given parameter does not provide definitive conclusions. Repeated measurements of NPs can show up to 100% variability in concentration in an individual patient [5, 40]. Mitral inflow velocities, tricuspid regurgitation velocity (TRV), and to a lesser extent LA volume index (LAVI) and e’ velocities can also change over time depending on preload and/or heart rate [31–34, 41–47]. Another issue regarding echocardiographic measurements would be intra- and interobserver variability [51–53]. Importantly, in chronic HFrEF, symptoms are observed during physical exertion, and thus measurements obtained at rest can lead to false negative results. Most non-invasive HFrEF definitions refer to assessment at rest with the possibility to proceed to exercise echocardiography if the results are inconclusive or if the risk is deemed intermediate [1, 4, 5]. Notably, when invasive exercise testing was implemented as a reference method, among patients finally diagnosed with HFrEF, almost half displayed elevation in pulmonary capillary wedge pressure (PCWP) only during exercise [24, 54]. This indicates that even the “gold standard” of HFrEF diagnosis, invasive hemodynamic study, can yield a high proportion of false negative results if performed only at rest.

The aforementioned problems are mirrored by a relatively poor agreement between different HFrEF diagnostic criteria: a patient diagnosed with HFrEF according to one definition, may be reclassified as not having HFrEF according to another [19, 21–24, 55]. Moreover, non-invasive HFrEF definitions vary significantly in their accuracy in identifying patients with invasively proven HFrEF, as well as in their predictive value for future cardiovascular events [19, 20–24, 55]. It seems that the best “validation” of a HFrEF definition would be a positive result of a randomized clinical trial showing a favorable effect of an intervention on prognosis in HFrEF — inclusion criteria in such a trial could automatically become diagnostic criteria for HFrEF.

**The first step towards a modern definition: The 2016 ESC guidelines**

The 2016 European Society of Cardiology (ESC) HF guidelines were revolutionary by distinguishing three clinical syndromes: HF with reduced (HFrEF), preserved (HFrEF), and mid-range ejection fraction (EF), with an unequivocal definition of each of these clinical entities [1]. The diagnosis of chronic HFrEF in a patient with an EF of ≥ 50% required the presence of HF symptoms and/or signs, elevation of NPs (B-type NP [BNP] ≥ 35 pg/mL or N-terminal pro-BNP [NT-proBNP] ≥ 125 pg/mL), and at least one of the following echocardiographic criteria: LA enlargement (LAVI > 34 mL/m²), LV hypertrophy (by LV mass index [LVMI]), or diastolic dysfunction (by E/e’ ratio and e’) [1]. Given the low specificity of LA enlargement and NP exclusionary cut-off points adopted in the guidelines, those criteria could be perceived as relatively “mild” with some potential for overdiagnosis. However, it seems reasonable for a new definition to include a wider spectrum of patients facilitating their accurate characterization and a thorough analysis to identify more specific subgroups. On the other hand, the definition itself was based on assessment at rest, which, in patients
with exertional symptoms, may have led to false negative results. In fact, in well compensated patients with HFpEF confirmed by invasive exercise testing, its sensitivity was found to be only 60% and specificity 75% [24].

An echocardiographic algorithm for the diagnosis of diastolic dysfunction: The 2016 ASE/EACVI recommendations

In 2016, less than two months after the release of the ESC guidelines on HF, the American Society of Echocardiography (ASE) and the European Association of Cardiovascular Imaging (EACVI) published recommendations on the echocardiographic evaluation of diastolic function (an update of a previous document from 2009) [4,56]. A simple algorithm was proposed for echocardiographic assessment of diastolic function in patients with an EF of ≥ 50% (Fig. 2A). The algorithm was based on four easily obtainable echocardiographic parameters: two tissue Doppler imaging (TDI)-derived, direct indices of LV diastolic dysfunction (reduced e’ velocity and increased E/e’ ratio) and two “indirect” parameters secondary to elevation of LA pressure (increased LAVI and TRV) [4]. Compared to the ESC guidelines, the ASE/EACVI algorithm did not account for LV hypertrophy nor, understandably, NP concentrations. Nevertheless, it was more specific for diastolic dysfunction, due to the requirement of three or four positive criteria to satisfy the definition, compared to only one positive echocardiographic criterion required to meet the ESC definition [1,4,24]. The ASE/EACVI algorithm also enabled echocardiographic estimation of LA pressure and grading of diastolic dysfunction based largely on mitral inflow pattern (Fig. 2B) [4]. In patients with dyspnea and grade I diastolic dysfunction (normal estimated LA pressure at rest), exercise echocardiography was recommended [4]. Importantly, the ASE/EACVI algorithm is the only one among the four discussed in this document which is designed for identifying and grading diastolic dysfunction rather than diagnosing HFpEF as a clinical syndrome.

The ASE/EACVI algorithm was validated against invasive measurements in a few studies, with sensitivity for elevation of resting LV filling pressures ranging from 69% to 87% and specificity ranging from 74% to 88%, which was significantly superior to clinical assessment [21–23]. However, when validated against invasive exercise testing, its sensitivity dropped to 34% (maintaining a high specificity of 83%) [24].

Evidence-based assessment of HFpEF probability: The 2018 H2FPEF score

Contrary to other HFpEF definitions based on expert consensus opinion, the H2FPEF score was derived from a cohort of 414 patients with an EF of ≥ 50%, who were referred for exercise RHC for unexplained dyspnea in Mayo Clinic (Rochester, MN, USA) [54]. The H2FPEF score includes six dichotomized, widely available variables (four clinical and two echocardiographic), which, if positive, are attributed one point, with the exception of atrial fibrillation (AF) and obesity (BMI of > 30 kg/m²), which are attributed three and two points, respectively (Table 2). Thus, the maximum score is nine points. For each score, the probability of invasively confirmed HFpEF was calculated, allowing justifiable exclusion of HFpEF in patients with total scores of 0–1, and establishing its diagnosis with reasonably high confidence (likelihood of > 90%) at scores of 6–9 [54].

In the original study, the H2FPEF score proved superior to the 2016 ESC definition, allowing accurate discrimination of HFpEF from noncardiac causes of dyspnea with area under the curve (AUC) in the receiver operating characteristic (ROC) analysis of 0.84 and 0.89 in the derivation and validation cohort, respectively [54]. Interestingly, inclusion of NT-proBNP cut-off points did not incrementally add diagnostic ability to the score [54]. This again confirms that, contrary to acute symptom exacerbation, in ambulatory patients with stable, exertional dyspnea, the discriminative value of NP measurements for HFpEF is relatively low because chronic HFpEF patients may have low NP concentrations, and patients with normal LV diastolic function can have elevated NPs due to AF or other comorbidities [35–40].

In subsequent studies, the H2FPEF score showed high sensitivity for clinically ascertained diagnosis of HFpEF, as well as predictive value for future HF-related events both in HFpEF and in non-HF patients with cardiovascular risk factors [57–60].

A comprehensive, stepwise approach to diagnosis: The 2019 HFA-PEFF algorithm

In 2019, the Heart Failure Association (HFA) of the ESC released a consensus recommendation for the diagnosis of HFpEF [5]. The proposed HFA-PEFF algorithm, presented in Figure 3, is a stepwise approach, including:
Figure 2. The 2016 American Society of Echocardiography/European Association of Cardiovascular Imaging (ASE/EACVI) diagnostic algorithm for: A. The diagnosis of diastolic dysfunction in patients with preserved ejection fraction. B. Grading of diastolic dysfunction and estimation of left atrial pressure (LAP) in patients with preserved ejection fraction and myocardial disease. Adopted from Nagueh et al., 2016 [4], modified; CAD — coronary artery disease; LAVI — left atrial volume index; TRV — tricuspid regurgitation velocity.
Step 1 (P): Pretest assessment

This step is consistent with an initial diagnostic work-up of patients presenting with dyspnea or other symptoms suggestive of HF, as recommended by the 2016 ESC guidelines on HF [1, 5]. Its goal is to identify individuals with potential diagnosis of HFpEF and exclude (or identify) alternative causes of symptoms (such as HFrEF, valvular disease, coronary artery disease, arrhythmias, pulmonary disease, anemia, etc.). This step encompasses clinical assessment, laboratory tests (including NPs if available), electrocardiogram, chest X-ray, and standard echocardiography. Clinical assessment includes evaluation of symptoms as well as risk factors for HFpEF (older age, obesity, arterial hypertension, metabolic syndrome with prediabetes/diabetes) and coexisting conditions. On the one hand, some comorbidities may imitate HF symptoms, and on the other hand, some are highly prevalent in HFpEF and thus strongly suggestive of HFpEF, even if they could themselves explain exertional dyspnea (obesity, AF). If NP measurement is available, lower cut-off points (BNP of 35 pg/mL or NT-proBNP of 125 pg/mL, consistent with the 2016 ESC guidelines on HF) are adopted in step 1 due to their higher sensitivity and negative predictive value [1, 5]. Still, almost one fifth of patients with invasively proven HFpEF had NT-proBNP below this threshold, and thus normal NP concentrations do not exclude chronic HFpEF, especially in obese patients [24, 35–40]. Standard echocardiography aims to exclude alternate cardiac causes of dyspnea, assess EF (with “preserved EF” defined as ≥ 50%), and identify features suggestive of HFpEF, such as nondilated LV with concentric remodeling or hypertrophy, and LA enlargement. If step 1 (P) indicates possible HFpEF, then step 2 (E) is indicated [5].

Step 2 (E): Echocardiographic and NP score

Step 2 is based on the HFA-PEFF scoring system with 0–2 points assigned for each of the three domains: 1) functional (echocardiography), 2) morphological (echocardiography or, less frequently, cardiac magnetic resonance), and 3) biomarker (NPs). In each domain, cut-offs for certain parameters have been proposed and attributed one (minor criterion) or two points (major criterion), as shown in Table 3. Importantly, one domain can contribute maximally two points, even if more major or minor criteria are fulfilled. A total score of 5–6 points is considered to be diagnostic for HFpEF, while a score of 0–1 points makes the diagnosis of HFpEF unlikely and should prompt assessment of other possible causes of symptoms. A score of 2–4 points requires further evaluation (step 3) using exercise testing (echocardiographic or invasive) [5].

In the HFA-PEFF score, different cut-offs for NPs and LAVI have been adopted for AF (vs. sinus rhythm), for e’ for patients aged ≥ 75 years (vs. younger patients), and, similarly to the ESC definition, for LVMi for women vs. men. For NPs, eight cut-off points are given: four for BNP and four for NT-proBNP, depending on heart rhythm (with cut-offs in AF three times higher than in sinus rhythm) and criterion type (major vs. minor) [5]. From the clinical perspective, the complexity of the score with multiple variables in each domain and diverse cut-off points for one variable might be considered a drawback hindering its use in eve-
Figure 3. The HFA-PEFF diagnostic algorithm. Adopted from Pieske et al., 2019 [5], modified; HFpEF — heart failure with preserved ejection fraction; ECG — electrocardiogram.
ryday practice. However, as stressed by the HFA Experts, not all parameters from each domain need to be available to calculate the score, and therefore the seeming abundance of parameters actually increases its practical utility because typically not all parameters are given in an echocardiographic report. Thus, HFpEF diagnosis actually requires only one major criterion from each domain (e.g. TRV > 2.8 m/s, LAVI > 34 mL/m$^2$, and NT-proBNP > 260 pg/mL for patients with AF) or two major criteria and one minor criterion (e.g. E/e’ of ≥ 15, LAVI > 34 mL/m$^2$, and NT-proBNP 125–220 pg/mL for patients with sinus rhythm). On the other hand, a definite exclusion of HFpEF would ideally necessitate evaluation of all parameters.

Notably, the HFA-PEFF score has, for the first time, included reduced absolute global longitudinal strain (GLS), an index of impaired systolic function, as a criterion for HFpEF diagnosis. Up to two thirds of HFpEF patients show abnormal GLS despite preserved EF [61, 62]. This reflects the complexity of HFpEF pathophysiology, with preclinical systolic dysfunction as yet another contributor to HFpEF syndrome [63–65].

The HFA-PEFF score was validated in two independent studies [55, 66]. The first study included two prospective cohorts and showed excellent sensitivity (99% for low-likelihood category, i.e. a total of 0–1 points) and specificity (93% for high-likelihood category, i.e. a total of 5–6 points) of the score with an AUC of 0.90 [66]. However, final HFpEF diagnosis in this study was not based on invasive measurements but mostly on echocardiography, NPs, and clinical judgement. Furthermore, both cohorts included patients with high pre-test probability of HFpEF with only a small control group of non-HFpEF patients (potential selection bias). Notably, more than one third of patients in both cohorts were classified in the intermediate-likelihood category (a total of 2–4 points) with.

Select only one score from each domain

Total score:

0–1 points: HFpEF unlikely → search for alternative causes of symptoms

2–4 points: intermediate probability → diastolic stress test (non-invasive or invasive)

5–6 points: HFpEF confirmed

AF — atrial fibrillation; BNP — B-type natriuretic peptide; GLS — global longitudinal strain; HFpEF — heart failure with preserved ejection fraction; LAVI — left atrial volume index; LVMi — left ventricular mass index; M — men; NT-proBNP — N-terminal proBNP; RWT — relative wall thickness; sPAP — systolic pulmonary artery pressure; SR — sinus rhythm; TRV — tricuspid regurgitation velocity; W — women
a need for step 3 of the HFA-PEFF algorithm to secure the diagnosis [66]. In the second study, the HFA-PEFF score was validated against exercise testing with invasive hemodynamic monitoring, showing only moderate accuracy, with an AUC of 0.73 [55]. One quarter of patients in whom HFpEF could have been ruled out based on the HFA-PEFF score (0–1 points) had elevated PCWP consistent with HFpEF diagnosis, and almost one fifth of patients deemed to have HFpEF by the score (5–6 points) had normal PCWP both at rest and during exercise [55].

Step 3 (F₁): Functional testing in the case of uncertainty

Step 3 is performed in patients who were attributed 2–4 points in the HFA-PEFF score (step 2), and encompasses exercise echocardiography and/or heart catheterization at rest and during exercise. Exercise echocardiography (preferably using a semi-supine bicycle) can show an elevation in LV filling pressures (by E/e’ ratio) during exercise, which can be accompanied by an increase in pulmonary artery pressure (estimated using TRV). An increase in the E/e’ ratio to ≥ 15 adds two points to the HFA-PEFF score calculated in step 2. An increase in the E/e’ ratio to ≥ 15 with a peak TRV of > 3.4 m/s adds three points to the HFA-PEFF score. A combined score from step 2 (E) and step 3 (F₁) of five points or more confirms HFpEF diagnosis. If the combined score does not exceed five points, invasive hemodynamic assessment is recommended. This includes right and/or left heart catheterization at rest, and — in the case of inconclusive results — exercise RHC. Diagnostic criteria for HFpEF include resting LV end-diastolic pressure (LVEDP) of ≥ 16 mmHg on left heart catheterization and/or mean PCWP of ≥ 15 mmHg on RHC (of note, the cut-off point for PCWP is consistent with the 2019 HFA-PEFF score). A comparison of HFpEF diagnostic criteria from different documents is shown in Table 4.

Is the 2016 ESC definition still valid?

The 2016 ESC HFpEF definition was much more liberal and less specific than the 2019 criteria adopted by the HFA. The ESC definition required only one echocardiographic criterion to be fulfilled, and cut-off points for LVMI and NPs were consistent with the 2019 HFA minor criteria [1, 5]. Thus, the 2016 ESC definition should have the advantage of higher sensitivity, and might be used for screening patients with symptoms suggestive of HF. The initial diagnostic work-up of a patient with suspected HF (including the cut-off points for NPs) proposed in the 2016 ESC HF guidelines was largely incorporated into step 1 (P) of the 2019 HFA-PEFF algorithm [1, 5].

A comparison of HFpEF diagnostic criteria from different documents is shown in Table 4.

Step 4 (F₂): Final etiology

In most patients, HFpEF is associated with typical demographic and clinical presentation, and is related to common risk factors (older age, arterial hypertension, obesity, and metabolic syndrome), but in some patients HFpEF may be a manifestation of specific heart muscle diseases, for example hypertrophic cardiomyopathy, infiltrative cardiomyopathies (such as amyloidosis, sarcoidosis, or hemochromatosis), storage diseases (such as Fabry disease, glycogen storage diseases, or Gaucher disease), radiation-induced cardiomyopathy, endomyocardial fibrosis, autoimmune diseases, and other genetic disorders. Such specific etiologies need always to be considered, especially in cases with atypical presentation or positive family history, and if suspected, should prompt implementation of advanced diagnostic measures. Depending on the suspected underlying cause of HFpEF, these might include cardiac magnetic resonance, 99mTc-DPD scintigraphy, positron emission tomography, cardiac or non-cardiac biopsies, and/or specific laboratory tests, including genetic testing [5].

Are the 2019 HFA-PEFF score and the 2016 ASE/EACVI algorithm compatible?

The 2016 ASE/EACVI algorithm refers to evaluation of LV diastolic function and relies purely on echocardiographic criteria [4]. On the contrary, the 2019 HFA-PEFF score was designed to diagnose HFpEF in symptomatic patients and requires both echocardiographic assessment and measurement of NPs [5]. As presented in Table 5, cut-off points for e’ and the E/e’ ratio in the two algorithms
are comparable [4, 5]. However, given the different rules of point attribution, as well as obligatory NP measurement in the HFA-PEFF score, the two algorithms are not interchangeable, and some patients diagnosed with HFpEF/diastolic dysfunction according to one of them might not necessarily fulfil criteria allowing its unequivocal diagnosis according to the other (see examples, Fig. 4). Nonetheless, patients diagnosed with diastolic dysfunction using the ASE/EACVI algorithm will have at least intermediate probability of HFpEF in the HFA-PEFF score (because they will score at least two points). Conversely, patients with HFpEF diagnosis based on the HFA-PEFF score (5–6 points) might theoretically have normal diastolic function according to the ASE/EACVI algorithm, e.g. if they had significant LV hypertrophy with high NP concentrations (major criteria) with preserved e’ velocities, low TRV, and LA that has not enlarged yet (E/e’ ratio is expected to be elevated with high NPs, although this is not always the case, see Fig. 4A). However, such a scenario seems less probable in clinical practice. Comparison of the diagnostic accuracy of the two algorithms, their mutual validation, and assessment of the proportion of reclassified cases should be the aims of future studies.

With a wider spectrum of echocardiographic parameters and NP measurement, the 2019 HFA-PEFF algorithm offers a more integrated approach to the diagnosis of HFpEF, which may prove more reliable, although this still needs to be confirmed. On the other hand, apart from diagnosing diastolic dysfunction (including preclinical diastolic dysfunction), the 2016 ASE/EACVI criteria enable its grading with an estimation of LA pressure, which, although not very accurate, is very useful in clinical practice, especially for follow-up of HF patients and assessment of efficacy of diuretic treatment.

Notably, this year, a modification of the 2016 ASE/EACVI algorithm was proposed by two of its authors, however, not as official recommendations [67].

Figure 4. Comparison of the American Society of Echocardiography/European Association of Cardiovascular Imaging (ASE/EACVI) algorithm and the HFA-PEFF score based on clinical cases. A. An 88-year-old man with exertional dyspnea, sinus rhythm, and CCS with a history of percutaneous coronary intervention. Resting echocardiography revealed EF of 51%, LVH (LVMI 125 g/m$^2$), RWT 0.48, reduced e’ velocities with E/e’ of 11, LAVI of 40 mL/m$^2$, and TRV of 2.71 m/s. NT-proBNP was 371 pg/mL. Based on the ASE/EACVI algorithm, echocardiography was inconclusive for the diagnosis of diastolic dysfunction (two of four criteria positive). Given E velocity of 0.5 m/s, estimated resting LA pressure can be classified as normal; therefore, symptoms could either be attributable to CCS or would require assessment with diastolic stress test (see Fig. 2B). However, according to the HFA-PEFF score (a total of six points), the patient can be diagnosed with HFpEF without proceeding to stress test. B. A 51-year-old woman with sinus rhythm and exercise intolerance. Resting echocardiography revealed EF of 65%, concentric LV remodeling (LVMI 69 g/m$^2$, RWT 0.49), normal e’ velocities with E/e’ of 6, and LAVI of 33 mL/m$^2$ (LA volume of 54 mL, BSA of 1.64 m$^2$). There was no detectable TR Doppler signal profile. NT-proBNP was 371 pg/mL. Based on the ASE/EACVI algorithm, echocardiography was inconclusive for the diagnosis of diastolic dysfunction (two of four criteria positive). Given E velocity of 0.5 m/s, estimated resting LA pressure can be classified as normal; therefore, symptoms could either be attributable to CCS or would require assessment with diastolic stress test. However, according to the HFA-PEFF score (a total of six points), the patient was classified as having normal diastolic function. However, according to the HFA-PEFF score, with a total of three points (two points for the biomarker domain and one point for the morphological domain), HFpEF probability is intermediate, and the patient requires diastolic stress test.
Do the European HFA-PEFF score and the American H2FPEF score refer to the same patients?

The two definitions share similarities: both use a combination of various parameters in the form of a scoring system, and both are based on a Bayesian approach, describing HFpEF likelihood rather than providing a straightforward diagnosis. Both are meant for evaluation of chronic, symptomatic patients (the H2FPEF score — those with unexplained dyspnea). However, there are some major differences between the two scores. First, the H2FPEF score is an evidence-based tool derived and validated in patients referred for RHC, while the HFA-PEFF score is an expert consensus-based concept. Second, the H2FPEF score is predominantly based on clinical profiles, while the idea behind the HFA-PEFF score is that hemodynamic abnormalities in HFpEF can and should be objectivized by echocardiography and NPs [5, 54]. Thus, the H2FPEF score could make a convenient bedside screening tool incorporated as step 1 (P) into the HFA-PEFF algorithm. Another premise for the use of the H2FPEF score as a screening method is its high sensitivity, resulting from the fact that almost half of the HFpEF patients in the derivation cohort had early-stage HFpEF with elevation of LV filling pressures only during exertion [54, 57]. Third, the effect of AF on the probability of HFpEF seems discordant in the two scores: in the H2FPEF score the presence of AF significantly increases the likelihood of HFpEF, while in the HFA-PEFF score it necessitates higher cut-off points of NPs and LAVI, decreasing the probability of HFpEF diagnosis at lower values. Thus, the same patient might even be classified at the opposing ends of the spectrum of HFpEF probability by each of the two scores. An elderly patient with unexplained dyspnea, AF, and a BMI of > 30 kg/m² would be attributed a total of six points in the H2FPEF score, satisfying the criteria for HFpEF; regardless of the echocardiographic result (and regardless of NP measurement, which is not required in this score) [54]. In the HFA-PEFF algorithm, such a patient would only complete step 1 (P) and would require

Figure 4 (cont.). C. A 75-year-old woman with atrial fibrillation. Resting echocardiography revealed EF of 57%, concentric LVH (LVMI 111 g/m², RWT 0.58), and e’ septal and lateral of 5 and 9 cm/s, respectively (reduced as per ASE/EACVI algorithm, but within the norm range for age as per HFA-PEFF score), with E/e’ of 16.4, LAVI of 42 mL/m², and moderate TR with TRV of 2.73 m/s. NT-proBNP was 849 pg/mL. According to the ASE/EACVI algorithm, the patient has diastolic dysfunction. This is consistent with the result of the HFA-PEFF score (six points, diagnosis of HFpEF); BSA — body surface area; CCS — chronic coronary syndrome; EF — ejection fraction; HFpEF — heart failure with preserved ejection fraction; LA — left atrium; LAVI — left atrial volume index; LV — left ventricle; LVH — left ventricular hypertrophy; LVMi — left ventricular mass index; NT-proBNP — N-terminal pro-B-type natriuretic peptide; RWT — relative wall thickness; TRV — tricuspid regurgitation velocity.
A thorough echocardiographic and NP assessment using the HFA-PEFF score (step 2 [E]), with higher cut-offs for NPs and LAVI due to AF [5].

A comparison of the two scores in an Asian population demonstrated high specificities of both scores (81% for the HFA-PEFF score and 88% for the H2FPEF score) with significantly higher sensitivity of the HFA-PEFF score (74%) than of the H2FPEF score (25%) [68]. This surprisingly low sensitivity of the H2FPEF score might be explained by the fact that Asian HFpEF patients are almost a decade younger and have a lower prevalence of obesity and AF (two and three points in the H2FPEF score, respectively) than their western counterparts [69]. Thus, predictive values of different scores may substantially vary depending on the population studied.

Practical considerations on clinical profiles

Analysis of the presented HFpEF definitions may lead to a few realizations regarding clinical characteristics, including female sex, obesity, and AF.

Heart failure with preserved EF is widely regarded as a disease of older women [70]. However, even though the proportion of women is higher than men in the HFpEF population (contrary to HFrEF), the incidence of HFpEF adjusted for age and other risk factors tends to be similar in women and men [16, 71–73]. Notably, female sex was not included as a criterion in any of the above presented scores or definitions [1–11, 54]. A higher proportion of women among HFpEF patients might result from their higher life expectancy [72]. However, estrogen deficiency has been postulated as one of the contributors underlying HFpEF development in post-menopausal women [74–76]. Among HFpEF patients, women have smaller LV dimensions with poorer diastolic reserve and higher LV filling pressures at rest and exercise [77].

Obesity should not be perceived as a sufficient explanation for breathlessness or low exercise capacity but as a strong risk factor of HFpEF [70, 71]. This is reflected by two points attributed for a BMI of > 30 kg/m² in the H2FPEF score [54]. Importantly, obesity can lead to NP concentrations that are normal or close to normal, even in the presence of HFpEF [1, 36, 38]. Unfortunately, this was not accounted for in the HFA-PEFF score [5]. Based on observations from hemodynamic studies, the existence of a distinct, obese phenotype of HFpEF has been postulated recently [78, 79].

Atrial fibrillation is highly prevalent in HFpEF — even more prevalent than in HFrEF [16, 80, 81]. This is because AF is not only a consequence of elevation of LA pressure and LA enlargement in the course of HF (regardless of EF), but also because AF and HFpEF share a common pathophysiological background and risk factors (older age, obesity, hypertension, diabetes) [82, 83]. However, AF can also be regarded as an important confounder in diagnosing HFpEF; first, because it can lead to an increase in NPs and LAVI even in the absence of HFpEF; and second, because it hinders echocardiographic evaluation of diastolic function [5]. Thus, as mentioned above, different scores represent different approaches to AF: the more “clinical” H2FPEF score recognizes it as a risk factor, while the HFA-PEFF score sees it as a confounding factor [5, 54].

Last but not least, even modern HFpEF definitions are, to some extent, “diagnoses of exclusion”. For example, the derivation cohort for the H2FPEF score included patients referred for RHC for “unexplained” dyspnea, i.e. after exclusion of HFrEF, valvular heart disease, pulmonary arterial hypertension, constrictive pericarditis, clinically relevant pulmonary disease, and other conditions that might have accounted for their symptoms [54]. Similarly, step 1 (P) of the HFA-PEFF algorithm assumes exclusion of other cardiac and non-cardiac causes of dyspnea [5]. This is understandable given the aforementioned low specificity of most currently available echocardiographic and biochemical parameters. Still, in the elderly, multimorbidity is highly prevalent, and even more so in patients with HFpEF [70–72]. A single patient may, and often does, have several comorbidities, apart from HFpEF, that might add to his/her symptoms, and all of them deserve recognition and treatment. Thus, validation of the presented HFpEF definitions should ideally be conducted in unsellected cohorts of symptomatic patients.

HFpEF definitions in clinical trials

Table 6 presents inclusion criteria applied in major HFpEF randomized clinical trials, which are largely inconsistent with the definitions reviewed above. Those trials included also a subset of patients that we nowadays refer to as HF with mid-range EF [6–11]. Analyzing inclusion criteria in those studies, over the years, an evolution of HFpEF definition can be seen, from more clinically based to objectivized by echocardiography and NPs.
Interestingly, prior HF hospitalization was (and still is) a common (although not always obligatory) criterion for inclusion, driven by the intent to recruit higher risk patients with more potential to prove benefits from treatment by event reduction. This approach also reflects the fact that HFpEF manifestation is more evident in the acute setting of symptom exacerbation, but on the other hand might have led to its overdiagnosis and loss of the effect of spironolactone on the primary endpoint in the TOPCAT (Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist) trial [8, 84]. For now, no treatment tested in clinical trials has demonstrated an improvement in survival in HFpEF, although some benefit was observed when analyzing other clinical endpoints (e.g. HF hospitalizations for candesartan, perindopril, and spironolactone) or specific HFpEF subpopulations (e.g. women for sacubitril-valsartan) [6, 8, 10, 85].

Similar to HFrEF, HFpEF is not a homogenous clinical entity, but encompasses a wide spectrum of underlying diseases ultimately leading to elevated LA pressure despite preserved EF. This heterogeneity of the HFpEF syndrome may, at least in part, account for disappointing results of clinical HFpEF trials [86]. It is postulated that the “one fits all” strategy may need to be changed to a more individualized approach based on phenotypic patient characterization including cardiac and non-cardiac comorbidities [87–91].

Conclusions: Which definition should we use?

The abundance of diagnostic criteria for HFpEF results from uncertainty regarding its underlying pathophysiology and lack of definition-guided treatment [1–11, 13, 54, 92]. At present, the 2019 HFA-PEFF algorithm constitutes the most comprehensive HFpEF definition, and its widespread use should be supported [5]. However, the 2016 ESC guidelines on HF can still be used in step 1 (pre-test assessment) of the HFA-PEFF algorithm [1]. Alternatively, implementation of the $H_F$ score in step 1 (P) might be advocated in patients with unexplained dyspnea, especially if NP measurements are not readily available [54]. Thus, in patients with suspected HFpEF, we suggest using the 2016 ESC HFpEF definition or estimation of HFpEF probability with the H2FPEF score for screening purposes by general practitioners, internists, geriatricians, or general cardiologists (as step 1 [P]), and if positive, verification of diagnosis using step 2 (E); the HFA-PEFF score) and, when indicated, step 3 (F) of the HFA-PEFF algorithm by an HF specialist.

The 2016 ASE/EACVI definition was less comprehensive than the new HFA-PEFF algorithm but had an important practical advantage: it enabled echocardiographers to establish or exclude the presence of diastolic dysfunction, grade it, and summarize their conclusions in an echocardiographic report (simply the presence or absence of diastolic dysfunction at rest) [4]. This facilitated confirmation or exclusion of HFpEF diagnosis for clinicians who might not be familiarized with detailed echocardiographic indices of diastolic function. In the 2019 HFA-PEFF score, echocardiographic parameters and NP concentrations are analyzed in conjunction, which potentially leads to some confusion among non-HF specialists, hindering everyday use of the score due to its complexity [5]. Thus, in patients evaluated for dyspnea, it might be reasonable for echocardiographers to summarize the results from the two echocardiographic domains (functional and morphological) of the HFA-PEFF score by providing the total number of points (0–4 out of 4 possible) in conclusions of an echocardiographic report. The attending physician could then simply add 0–2 points depending on NP concentration to obtain the final result of the HFA-PEFF score.

Studies validating the HFA-PEFF score against invasive measurements, with comparison to the ASE/EACVI algorithm and the $H_F$ score, are warranted. The future will show whether this HFpEF definition will hold or whether it will be replaced by new diagnostic criteria — maybe originating from a positive randomized clinical trial?
