ABSTRACT

INTRODUCTION: The prevailing COVID-19 pandemic forces paramedics to take medical rescue operations using personal protective equipment (PPE) for aerosol-generating procedures (AGP). The use of PPE-AGP may reduce the effectiveness of the procedures performed, including airway management, intravascular access, or chest compression.

The goal of the current study was to compare the quality by which a chest compression during simulated COVID-19 resuscitation while wearing PPE-AGP. A secondary goal was to assess provider preferences with standard versus OHD chest compression methods while wearing PPE-AGP.

METHODS: This is a randomized cross-over single-blinded study involving 37 paramedics performing 2-min continuous chest compression using two methods: the standard chest compression (CC) method during which the rescuer takes a position to the side of the victim (STD) and over-the-head position (OHD). During cardiopulmonary resuscitation, study participants wore Class C PPE-AGP. Both the order of study participants and compression methods were random. The results were blinded before statistical analysis. The compression rate per minute (CPM), CC depth as well as full chest recoil were measured. The analysis was undertaken using STATISTICA (V13.3EN).

RESULTS: Mean chest compression depth using distinct CC methods varied and amounted to 42 ± 2mm for STD vs. 46 ± 4mm for OHD (p < 0.001). Chest compressions based on the OHD method were associated with a lower frequency of chest compressions (107 ± 7CPM) compared with STD (114.5 ± 8; p< 0.001). A higher percentage of full chest recoil was observed in the case of STD (42 ± 6%) than in the case of OHD (34 ± 10%).

CONCLUSIONS: Based on the current simulation trial, it is impossible to clearly determine which method (STD vs. OHD) is more effective in resuscitation with PPE-AGP. Paramedics wearing PPE-AGP achieved better chest compression depth for OHD compared to the STD, however, OHD resuscitation causes a lower degree of full chest relaxation. A further well-designed clinical study looking at efficacy, safety, and outcomes is needed to confirm current results.

INTRODUCTION
The outbreak of coronavirus disease 2019 (COVID-19) has become a primary challenging public health issue [1]. On March 11, 2020, the World Health Organization declared that the pandemic of COVID-19 had become a public health emergency of global concern. As of September 2, 2020 COVID-19 has been reported with a total of 25,835,301 confirmed cases and over 858,661 deaths. New coronavirus SARS-CoV-2 is mainly transmitted through 1) Direct exposure with cough, sneeze, and droplet inhalation within a range of about 1.8 meters; and 2) Contact transmission through contact with oral, nasal, and eye mucous membranes [2, 3]. Current personal protective equipment (PPE) and infection control guidelines from the WHO is based on the assumption that the primary mechanism of transmission is direct and indirect droplet spread. In this situation, paramedics working in the pre-hospital setting should treat any patient as potentially infected with the SARS-CoV-2 virus [4, 5]. The WHO advises that airborne transmission can occur, but only when aerosol-generating procedures (AGP) are performed [6]. AGPs are those that have the potential to generate aerosols and droplets that can spread respiratory pathogens. In this context, cardiopulmonary resuscitation (CPR) is a complex procedure that is particularly dangerous for medical personnel. As the study by Borkowska et al. examining the effectiveness of cardiopulmonary resuscitation during the COVID-19 pandemic, the return of spontaneous circulation (ROSC) in prehospital setting was observed only in 9.4% of resuscitated patients [7]. In turn, Baldi et al. indicating the OHCA issues in Italy indicate that during the first 40 days of the COVID-19 outbreak (February 21 through March 31, 2020) with those that occurred during the same period in 2019 and indicate a 58% increase rate of OHCA in 2020 [8]. Low patient survival may be caused by both the negative consequences of SARS-CoV-2 infection, as well as the reduced effectiveness of the procedure performed by Emergency Medical Service personnel wearing PPE-AGP.

The goal of the current study was to compare the quality by which a chest compression during simulated COVID-19 resuscitation while wearing PPE-AGP. A secondary goal was to assess provider preferences with standard versus OHD chest compression methods while wearing PPE-AGP.

METHODS
Study Population and Setting
The study population consisted of paramedics participating in the training of Advanced Cardiovascular Life Support (ACLS) conducted according to the AHA guidelines [9]. Inclusion criteria were: a) consent to participate in the study, b) active paramedic status, c) minimum one year of experience in EMS teams. Exclusion criteria were: a) refusal to consent, b) presence of medical concerns precluding the ability to participate, including pregnancy or asthma, c) symptoms or suspicion of viral infection.

Study Design
A prospective, randomized, crossover single-blinded simulation trial was conducted. The protocol of this trial was approved by the Institutional Review Board of the Polish Society of Disaster Medicine (No. 22.01.20.IRB). The study was conducted according to the Consolidated Standards of Reporting Trials (CONSORT) statement (Suppl. 1).

Before beginning the simulation portion of the study, all participants were asked to complete a short questionnaire concerning previous experiences with clinical resuscitation as well as PPE-AGP using. Additionally, all participants participated in a 60-minute training session reminding the principles of cardiopulmonary resuscitation following the guidelines of the American Heart Association (AHA) [9], as well as the demonstration of the correct donning of the PPE-AGP suit and performing chest compression using the STD and OHD method (Fig. 1).

After the demonstration session, participants were randomized to STD or OHD while wearing a Tychem F Level-C (DuPont, Wilmington, USA) suit, airway protection N95 respirator (3M Poland, Kajetany, Poland), face shield (3M Poland, Kajetany, Poland) including double nitrile gloves (MedaSEPT®, Poznan, Poland).

The participants were then asked to perform a 2-minute cycle of continuous chest compression (CCC) using one method, then had a 30-minute
break, and then performed chest compression using another method. The detailed procedure of trial randomization is presented in Figure 2.

All chest compressions were performed on a Sim-Man 3G (Laerdal Inc., Stavanger, Norway) adult simulator. The simulator was placed on a flat surface to simulate sudden cardiac arrest at home.

After performing chest compression both methods, each participant completed the post-intervention questionnaire regarding perceptions of ease of chest compression while wearing PPE-AGP.

Outcomes and Data Collection

The primary outcome measure was the quality of chest compression, which consisted of the following parameters: chest compression rate, chest compression depth as well as chest recoil. The values indicated in the AHA guidelines [9] were used as reference values. Accordance with those guidelines, chest compression rate should be between 100 and 120 compressions per minute (CPM), the depth of chest compressions should be 5 to 6 cm, and after each compression should be followed by full relaxation of the chest.

The chest compression quality data was recorded in real-time using the simulator control software — Laerdal Learning Application (LLEAP software, v.7.1.0; Laerdal Inc, Stavanger, Norway).

De-identified participants’ data were entered into Macintosh Excel Database (Microsoft Excel for MAC 2020, v.16.40; Microsoft Inc., Redmond, WA, USA). Data were correlated with questionnaire response data by the use of pre-assigned participant numbers.
Statistical analysis and Sample Size Calculations

Sample size calculations were performed based on a two-sided paired t-test assuming 80% power and a significance level of 0.05. Assumptions for expected results were based upon the work of Malysz et al. [10]. Those calculations indicated that a sample size of 32 participants would be required to power the trial adequately to detect a difference of 5 millimeters between the two modalities. To ensure a safety margin, we recruited 37 participants in this study.

All calculations were done with the STATISTICA software package (v.13.3EN; Tibco Inc, Tulsa, OK, USA). For statistical analysis, the data was blinded. Continuous features were summarized with means and standard deviations. Categorical features were summarized with frequency counts and percentages. The Kolmogorov-Smirnov test was applied to test data for normality. Fisher Exact Tests were used to compare resident survey responses. We compared qualitative variables by Fisher exact test and Kruskal-Wallis test. Continuous data, including the time for the successful intravascular access, were analyzed using analysis of variance (ANOVA) testing. All tests were two-sided and p values less than 0.05 were considered statistically significant.

RESULTS

The study involved 37 paramedics whose mean age was 31 ± 7.5 years and mean work experience in EMS was 6.7 ± 4.5 years. All participants in the study declared their experience in the field of CPR in clinical settings. None of the study participants had experience with chest compression wearing PPE-AGP before study entry.

A detailed summary of the results of chest compression parameters is presented in Table 1. Mean chest compression depth using distinct CC methods varied and amounted to 42 ± 2 mm for STD vs. 46 ± 4 mm for OHD (p < 0.001). Chest compressions based on the OHD method were associated with a lower frequency of chest compressions (107 ± 7CPM) compared with STD (114.5 ± 8; p < 0.001). A higher percentage of full chest recoil was observed in the case of STD (42 ± 6%) than in the case of OHD (34 ± 10%). This difference was statistically significant (p < 0.001). The differences incorrect hand placement between STD and OHD were not statistically significant.

Most people (58.8%) indicated OHD as the preferred method during true CPR. The remaining people indicated the STD method as the preferred method.

DISCUSSION

The aim of the study was to compare two techniques of chest compression (STD vs. OHD) performed by paramedics wearing PPE-AGP. The prevailing COVID-19 pandemic causes that in the case of OHCA paramedics should perform CPR in protective suits. To the authors’ knowledge, this is the first STD vs. OHD under the conditions of use personal protective equipment against aerosol-generating procedures. Performing medical procedures when healthcare workers are wearing PPE-AGP may reduce the effectiveness of the procedures performed by extending the duration of these procedures as well as reducing the effectiveness of individual attempts to perform the procedure. This applies to both obtaining intravascular access [11], advanced airway management [12], as well as the effectiveness of chest compression [13]. Chen et al. [14] indicated significant deterioration of CC performance in HCWs with the use of a level-C personal protective equipment, which may be a disadvantage for enhancing the survival of cardiac arrest. In turn, a study by Donoghue et al. shows that during a clinically appropriate 2-minute period, neither CC quality nor self-reported fatigue worsened to a significant degree in providers wearing PPE [15]. Donoghue also indicates that that
Pediatric Basic Life Support recommendations for CC providers to switch every 2 minutes need not be altered with PPE use. The research of Malysz et al. [13] indicates that in the case of adult resuscitation, the use of PPE reduces the quality of chest compression, including a reduction in the depth of chest compressions and the correctness of chest relaxation with time. The differences between these two studies can be explained by the fact that resuscitation was carried out concerning the various simulators: an adult and a child. In the study by Malysz et al. an adult simulator was used, whose cardiopulmonary resuscitation requires much more effort than the resuscitation of a child. On the other hand, Dong-hue indicates that the depth of chest compression did not decrease significantly over time, however, according to the analysis of the data obtained by him, chest compression was performed based on too shallow chest compressions, which were on average 2.2 cm, while the guidelines of resuscitation for 5-years old child recommend that the CC depth be between 1/3 to 1/2 of the anteroposterior diameter of the chest, corresponding to a depth of at least 5cm [16]. Nevertheless, it is clear that the returning of the spontaneous circulation (ROSC) in patients experiencing cardiac arrest is dependent on the quality of the CPR they receive. However, a number of investigations have demonstrated that rescuers develop immediate fatigue during CPR and the quality of CC declines rapidly after 1 to 3 min of CPR [17]. Abelairas-Gómez et al. showed that a simple strength training program has a significant impact on the quality of chest compressions and its maintenance over time [18]. The analysis of the performed examination showed a statistically significantly greater depth of chest compressions during compression performed by OHD. This may be due to the force applied to the chest being directed differently, thus exerting more pressure on the chest than is the case with an STD. Another parameter, apart from the depth of chest compressions, influencing the quality of chest compression is the CC rate per minute. The chest compression rate was also associated with the return of spontaneous circulation [19, 20]. CPR guidelines performer by AHA as well as ERC recommends that the CPR be greater than 100CPM, but not greater than 120CPM [21, 22]. Despite the existence of differences in the rate of chest compression despite the STD and OHD groups, these rates were within the recommended range. Despite subsequent editions of the CPR guidelines, there is still no consensus among scientists regarding the optimal rate of chest compression. As indicated Solevåg et al. [23] and other authors, a higher CC rate (i.e. over 120/min) is also more fatigueing, which affects CC quality [24]. In turn, a study by Kilgannon et al. conducted in in-hospital cardiac arrest adult patients, a chest compression rate of 121-140CPM had the highest odds ratio of ROSC [25]. In the case of OHCA, Idris et al. indicated that compression rates between 100 and 120CPM were associated with the greatest survival to hospital discharge [19].

In this study, the continuous chest compression technique was selected. According to the ERC and AHA guidelines, efforts should be made to minimize interruptions in chest compressions. Moreover, as evidenced by Ewy et al. [26] research, CCC compared with 30:2 compressions-to-ventilations cardiopulmonary resuscitation improved neurological outcome. Wang et al. in a prospective, randomized animal study in the first 12 minutes of CPR, continuous compressions could maintain relatively better coronary perfusion pressure, PaO2, and global ventilation/perfusion values than 30:2 cardiopulmonary resuscitation [27]. The above advantage of continuous chest compressions over 30:2 resuscitation was also confirmed in other studies [28-30]. However, as the study by Liu et al. shows, chest compression quality decreased significantly faster when performing CCC compared to 30:2 method [31]. Therefore, the person compressing the chest should be changed every two minutes or sooner.

Another parameter influencing the quality of chest compression is full chest recoil (FCR), which was independently associated with improved survival and favorable neurologic outcome at hospital discharge after adult OHCA [32]. In our study, the correctness of chest relaxation in both STD and OHD was insufficient, and in the case of OHD, a statistically significant reduction in the correctness of FCR was observed. This may be because paramedics tend to lean excessively on the patient’s chest in over-the-head resuscitation. The above-mentioned and described parameters of chest compression, such as the depth of chest compressions, the frequency of compression or the correctness of chest relaxation are extremely important and affect the quality of the compression and thus the effectiveness of the entire CPR, however, they should not be treated individually—but try to perform CPR based on all parameters of chest compression at the same time [33, 34].
Limitations and Strengths

Limitations of the medical simulation trials have been previously described [13]. In addition, only a group of paramedics participated in the study, however, it was a deliberate action dictated by the fact that paramedics are the first line of contact with OHCA patients and are relatively often forced to undertake resuscitation measures in pre-hospital conditions, and in the time of the prevailing COVID pandemic -19, these procedures should be performed in PPE-AGP.

The study also has strengths. To the authors’ knowledge, this is the first study to evaluate STD vs. OHD chest compression methods by paramedics while wearing PPE-AGP. Another strong point of the study is its randomized cross-over nature and the fact that it was a single-blinded study.

CONCLUSIONS

Based on the current simulation trial, it is impossible to determine which method (STD vs. OHD) is more effective in resuscitation with PPE-AGP. Paramedics wearing PPE-AGP achieved better chest compression depth for OHD compared to the STD, however, OHD resuscitation causes a lower degree of full chest relaxation. A further well-designed clinical study looking at efficacy, safety, and outcomes is needed to confirm current results.
