Abstract

We describe the arterial supply of a human kidney harvested post-mortem from a 75-year-old female volunteer body donor. The kidney was analysed with contrast-enhanced computed tomography, and corrosion casting was used to reveal the kidney’s angio-architecture. In the left kidney, we observed four renal arteries, each originating directly from the abdominal aorta. Three renal arteries, including the main renal artery, coursed through the renal hilum, and the fourth renal artery reached the lower kidney pole. The supply areas of each of the four renal arteries were analysed with a 3D reconstruction of computed tomography images and with corrosion casting. There were no clear boundaries between the areas supplied by the four renal arteries because their branches overlapped in most kidney segments.

Key words: renal artery, accessory, supernumerary, anatomical variation, corrosion casting, CT
INTRODUCTION

The anatomy of the human kidney arterial supply can vary substantially between people [3, 18, 22, 32], and this variation is an interesting research subject. Awareness of the many anatomical variants of the renal vascular system is important in the diagnosis of kidney diseases, and it helps understand why some patients have unusual clinical presentations. Knowing the anatomy of the renal vessels is particularly important in kidney transplantation, in which an accurate radiological evaluation of these vessels is essential to plan surgery [5, 18, 28].

Based on data from previous studies, the kidney is supplied by a single artery in 75% of cases (70% to 85%), more often the right kidney. In the remaining 25% of cases (20% to 30%), at least two arteries supply one kidney. In ~20% of cases (14% to 23%), the kidney is supplied by two renal arteries originating from the abdominal aorta; in ~2.5% of cases (1% to 4%), by three renal arteries; and in only < 1% of cases, by four renal arteries [5, 8, 18, 29]. The occurrence of additional renal arteries depends on the sex and race [23].

CASE REPORT

We examined a human kidney harvested post-mortem from a 75-year-old female volunteer body donor (Fig. 1). The kidney was fixed in a preservative medium (10% formalin + 40% alcohol + 90% glycerol) and then analysed with contrast-enhanced computed tomography. Special radiographic procedures using contrast media are used in certain cases to delineate internal structures. A contrast agent was used in the study - OMNIPAQUE 350 (contains 755 mg of iohexol equivalent to 350 mg of organic iodine per ml – each milliliter of iohexol solution contains 1.21 mg tromethamine and 0.1 mg edetate calcium disodium with the pH adjusted between 6.8 and 7.7 with hydrochloric acid or sodium hydroxide. Osmolality from approximately 2.2 to 3 times that of plasma (285 mOsm/kg water) or cerebrospinal fluid (301 mOsm/kg water), solution is hypertonic in the conditions of use). We injected about 10 ml of 3% solution of the contrast agent into each of the renal arteries, and then the arteries were ligated. The CT examination was performed using SOMATOM Definition AS (Siemens) and analysed with SYNGO Multi-Modality CT Workstation (Siemens). We used corrosion casting to visualize the blood vessels. We filled the blood vessels with latex (LBS 3060) and used 10% KOH + 5% H2O2 for soft tissue digestion at about 38 ° Celsius for a week. Based on computed tomography images,
we obtained a 3D reconstruction of the renal arterial supply system (Fig. 2), and the corrosion cast showed the angio-architectonics of the kidney (Fig. 3).

We examined both the courses and supply areas of the four renal arteries originating directly from the abdominal aorta and supplying individual kidney segments. In addition, for each renal artery, we measured both the distance from its origin in the abdominal aorta to the aortic bifurcation and its external diameter at the origin (Table I). We found that three renal arteries coursed through the renal hilum. The artery with the largest diameter (5.1 mm) was considered the main renal artery (Fig. 1, LRA2). The other two arteries in the renal hilum, i.e., LRA1 (4 mm in diameter) and LRA3 (4.4 mm in diameter), were considered accessory renal arteries (Fig. 1). The three renal arteries that coursed through the renal hilum branched off directly from the aorta at a distance from the aortic bifurcation of 105 mm (LRA1), 100 mm (LRA2), and 90 mm (LRA3). The fourth renal artery branched off from the aorta 35 mm from the aortic bifurcation, i.e., below the other renal arteries (Fig. 1, Table I). One of the renal arteries (LRA1) supplied mainly the posterior renal segment and, to a lesser extent, the inferior renal segment. The main renal artery (LRA2) supplied a substantial part of the kidney parenchyma, i.e., the apical and anterosuperior segments, and part of the anteroinferior segment. Another renal artery (LRA3) supplied the posterior segment and part of the inferior segment, which was the smallest supply area of all four renal arteries. The renal artery that joined the kidney near its lower pole (LRA4) supplied mainly the inferior segment and part of the anteroinferior segment, additionally an unusual course of the left ureter was observed - it crosses anteriorly LRA4 (Fig. 1). The computed tomography images and the corrosion cast both showed that there were no clear borders between the blood supply areas in the kidney, because the arteries were interconnected and had overlapping branches - particularly the interlobular arteries. Only the apical renal segment received blood supply from a single artery (the "main" renal artery). Moreover, a substantial part of the inferior renal segment received blood supply from the lowest additional renal artery (LRA4, Fig. 2).

**DISCUSSION**

Typically, single renal arteries branch off from both sides of the aorta and then bifurcate, near the renal hilum, into the anterior and posterior branches, which divide further into segmental arteries supplying different renal segments. It is common to see
more than one renal artery supplying a single kidney, and previous investigators described cases with renal arteries of varying numbers and courses [18, 22, 26-29]. The frequency of multiple renal arteries is determined by the feature of population. For example, in Caucasian and African populations a high incidence of multiple renal arteries is observed (30-40%), compared to Indian population (13.5%) [22, 27]. The frequency of presence of multiple renal arteries varies widely with ethnicity. According to Gulas et al. [7], range of the frequency of multiple renal arteries depending on ethnicity is between 4% (Malaysians) and 61.5% (Indians). In Polish population, the variability of multiple renal arteries seems to be between 11.2% and 38.3% [7, 25].

The classification of additional renal arteries is ambiguous, and different investigators use different terms to describe additional renal arteries, which hinders research on the subject. For example, Merklin and Michels [14] distinguish "supernumerary" arteries, whereas Graves [6] describes each additional renal artery arising from the abdominal aorta as "accessory" and those arteries not arising from the aorta as "aberrant". Herein, we used the classification of additional renal arteries put forward by Satyapal et al. [23] and Özkan et al. [18]. In this classification, additional renal arteries fall into two categories: (1) early division arteries, i.e., those branching off from the main renal arteries into segmental branches more proximally than the renal hilum; and (2) extra renal arteries, which are further classified as hilar (accessory) arteries and polar (aberrant) arteries. Hilar arteries, along with the main renal artery, enter the kidney through the renal hilum, whereas the aberrant arteries run directly towards the renal capsule and do not enter the renal hilum. Based on these criteria, the LRA4 artery described herein can be classified as an aberrant artery. Kidneys supplied by more than one artery can have other anatomical variations, such as more than one vein or ureter [24]. We, however, did not find such anatomical variants in the presented case. The anatomical variations of renal arteries are much more common than the variations of renal veins [11]. According to Bordei et al. [2], the former occur eight times as often as the latter. Rossi et al. [21] put forward that the common occurrence of vascular changes in the kidneys may be due to the disturbances of kidney migration early in the development of blood vessels, which may lead to the formation of additional renal arteries. Moreover, Satyapal et al. [23] propose that an abnormal spatial arrangement of the kidney promotes the development of abnormal blood vessels.
Our description of four renal arteries supplying one kidney is very rare among the existing reports on the variations of renal arterial supply; it is not, however, the only such description [5, 19-20, 25, 29]. Previous investigators reported many interesting variants of the renal arterial supply. Kinnunen et al. [12] described one of the most interesting cases, in which ten arteries supplied one kidney. Miclaus and Matusz [15] described a 58-year-old man with four renal arteries supplying each kidney. Rossi et al. [21] described a 23-year-old male living donor candidate with four arteries supplying the left kidney and three arteries supplying the right kidney. Koplay et al. [13] presented a case of a 36-year-old patient with seven renal arteries: three arteries on the right and two arteries on the left branched off from the abdominal aorta; one artery on the left branched off from the lower mesenteric artery; and one artery on the right, from the common iliac artery. Orlando et al. [17] described a kidney transplant recipient with six arteries - the first instance of successful transplantation of a kidney with more than four arteries [1]. Mishra et al. [16] found five renal arteries in an 18-year-old woman undergoing computed tomography (three right and two left arteries). In a post-mortem examination of a 61-year-old man, Jeon et al. [10] observed three right and two left renal arteries with asymmetric origin.

Other studies support these observations [5]. Other authors [19-20], however, indicate that renal arteries show greater variability on the left side compared with the right side. Saldarriaga et al. [22] and Satyapal et al. [23] found additional renal arteries more often on the left than on the right side. In our case, the additional renal vessels occurred on the left side as well. In the study by Jeon et al. [28], the distance from the origin of additional renal arteries to the aortic bifurcation ranged between 30 mm and 118 mm, and the external diameter of these arteries at their origin ranged from 3 mm to 7 mm. In the study by Mishra et al. [16], this diameter ranged between 2.5 mm and 4.3 mm. Additional inferior aberrant renal arteries are rare. Vilhova et al. [30] found that superior aberrant renal arteries occurred more often than did inferior aberrant renal arteries (22% vs. 4.4%), and Budhiraja et al. [4] reported similar figures. Other studies, however, reported a more frequent occurrence of inferior aberrant renal arteries compared with that of superior aberrant renal arteries [9, 31]. Aberrant renal arteries usually have smaller diameters than do the main renal arteries entering the kidney through the renal hilum [26]. In some people, aberrant renal arteries may cause ureteral obstruction leading to hydronephrosis, which is an important clinical problem [26].
CONCLUSIONS

In conclusion, we described a rare occurrence of a kidney supplied by four arteries. This is an additional source of information that can have clinical implications. Clinically, one should take into account that renal arteries have many anatomical variants, which is important in kidney disease diagnosis, renal vessel surgery, and kidney transplantation.
