[Received: 6 December 2018; Accepted: 7 February 2019]

Background: Traumatic brain injury (TBI) leads to neuronal damage and neurological dysfunction. The aim of our study was to investigate the antioxidative effect of honokiol on TBI in rats with biochemical, histopathological and immunohistochemical methods.

Materials and methods: Sprague–Dawley rats were subjected to TBI with a weight-drop device using 300 g/1 m weight/height impact. Forty-five rats were divided into three groups as control group, TBI group and TBI + honokiol group (5 mg/kg/day, i.p.). Honokiol (5 mg/kg) dissolved in dimethyl sulfoxide (DMSO) was intraperitoneally administered to rats for 7 days after the trauma. At the end of experiment, blood samples were taken from the animals and analysed with various biochemical markers.

Results: Histopathological examination of the trauma group revealed some degenerated pyramidal cells, dilatation and congestion in blood vessels, hyperplasia in endothelial cells, inflammatory cell infiltration around the vein and disruptions in glial extensions. In TBI + honokiol group, pyramidal neurons showed a decrease in degeneration, slight dilatation in blood vessels, improvement of endothelial cells towards the lumen, and reduction of inflammatory cells in the vessel. In TBI + honokiol group, vascular endothelial growth factor expression was positive in the endothelial and few inflammatory cells of the mildly dilated blood vessels. In the blood brain barrier deteriorated after trauma, it was observed that the glial foot processes were positive expression and extended to the endothelial cells in the TBI + honokiol group.

Conclusions: Glial fibrillary acidic protein expression showed a positive reaction in these processes. Considering the important role of antioxidants and inflammatory responses in cerebral damage induced by traumatic head injury, honokiol is thought to be important in decreasing lipid peroxidation, protecting the membrane structure of blood brain barrier, degeneration of neurons and glial cells. (Folia Morphol 2019; 78, 4: 684–694)

INTRODUCTION

Traumatic brain injury (TBI) is a health problem known as the cause of mortality and disability in young people. Primary and secondary injury cascades that cause delayed neuronal dysfunction, synapse loss and cell death are associated with TBI [1, 39]. Secondary damage develops within the minutes to days following the primary insult, release of the inflammatory mediators, formation of the free radicals, excessive release of the neurotransmitters (glutamate and aspartate), influx of calcium and sodium ions into neurons, and dysfunction of mitochondria [22]. At a cellular level, the biphasic nature of secondary injury is mediated by numerous disturbed pathways which include: excitotoxicity caused by an excess of the neurotransmitter glutamate; free radical generation by dysfunctional mitochondria, causing damage to proteins and phospholipid membranes of neurons and glia; the neuroinflammatory response which takes place due to both brain parenchyma and systemic immunoactivation [22, 31]. Glutamate is an excitatory amino acid which is known to play a role in the pathological events, increasing brain-blood barrier permeability and the occurrence of oxidant damage. Previous studies have shown that glutamate antagonists may be beneficial in several conditions, such as ischaemia, sepsis and trauma [1, 22]. The neuroinflammation is closely related to the overproduction of the reactive oxygen species which cause many neuropathologies. Free radicals damage various cellular components, including proteins, lipids and deoxyribonucleic acid. Antioxidants and anti-inflammatory drugs were widely studied in neurotrauma models [31]. After trauma, depending on the degree of brain damage, neuroinflammation, cerebral edema and blood-brain barrier fragmentation occur. Vascular endothelial growth factor (VEGF) is a trophic factor that is expressed in the central nervous system after injury [10] and induces angiogenesis [34]. Inhibition of VEGF expression after trauma may exacerbate neuronal and glial injury [23]. However, increased endogenous VEGF interacts with ischaemic vessels with its receptors and contributes to the deterioration of the blood-brain barrier and subsequent leakage [51].

Glial fibrillary acidic protein (GFAP) is an intermediate filament protein found in the skeleton of astroglia. Data from studies have shown that increased local tissue GFAP immunoreactivity is a sensitive indicator of neuronal damage and its increase is considered to be a determinant of reactive astrocytosis. GFAP level in blood fluid increases when cerebral tissue or spinal cord cells are damaged due to trauma or disease [15, 41, 50]. This marker is in fact an indicator of the reaction of astrocytes in the form reactive gliosis.

Honokiol is a natural biphenolic compound that is isolated from magnolia bark and has been used in the traditional Chinese and Japanese medicine as an antibacterial, antiemetic, antidepressant, antithrombotic, and anxiolytic agent. Studies have shown therapeutic effects including antioxidative and anti-inflammatory activities for honokiol [16, 27, 28].

Traumatic brain injury animal models are important in developing diagnostic and therapeutic strategies for understanding the pathophysiology of brain shocks [40]. In this study, antioxidative effects of honokiol on neuronal structures and changes in blood-brain barrier were investigated in TBI. In this study, we aimed to investigate antioxidative effects of honokiol on neuronal structures in a TBI model in rats with biochemical, histopathological and immunohistochemical methods.

MATERIALS AND METHODS

Animals

Every single surgical methodology and the consequent care and healing of the animals utilised as a part of this investigation were in strict understanding with the National Institutes of Health (NIH Publications No. 8023, revised 1978) rules for animal care. All techniques performed in this examination were approved by the Ethics Committee for Animal Experimentation of the Faculty of Medicine at Dicle University, Turkey. Male Sprague-Dawley rats (250–280 g) were housed in an air-conditioned room with 12-h light and dark cycles, where the temperature (23 ± 2°C) and relative humidity (65–70%) were kept constant. All rats at the end of experiment were healthy and no difference in food/water consumption and body weight gain between experimental and control rats were observed.

Traumatic brain injury model

Sedation procedure. The animals were anaesthetised by an intraperitoneal injection of 5 mg/kg xylazine HCl (Rompun, Bayer Health Care AG, Germany) and 40 mg/kg ketamine HCl (Ketalar, Pfizer Inc., USA), and were allowed to breathe spontaneously. A rectal probe was inserted, and the animals were
positioned on a heating pad that maintained the body temperature at 37°C.

Three groups (15 rats per group) were arranged as below:

— **Control group**: Isotonic saline solution (an equal volume of honokiol) was administered i.p. for 7 days;

— **TBI group**: The widely used diffuse brain injury model described by Marmarou et al. [31] was used. Briefly, a trauma device which works by dropping a constant weight from a specific height through a tube was used. A weight of 300 g was dropped from a 1 m height, which can induce mild trauma, as shown by Ucar et al. [46];

— **TBI + honokiol group**: Honokiol (5 mg/kg; Sigma-Aldrich Inc., St. Louis, MO, USA) dissolved in dimethyl sulfoxide (DMSO) was intraperitoneally administered for 7 days after the trauma. After 7 days, all animals were sacrificed by an intraperitoneal injection of 5 mg/kg xylazine HCl (Rompun, Bayer HealthCare AG, Germany) and 40 mg/kg ketamine HCl (Ketalar, Pfizer Inc., USA). After TBI, blood samples were taken from the animals and analysed with various biochemical markers. Then, parietal lobe of the brain cortex were rapidly removed. For the histological examination, brain tissues were fixed in 10% formaldehyde solution, post-fixed in 70% alcohol, and embedded in paraffin wax. The sections were stained with haematoxylin-eosin (H&E).

**Evans blue assay for blood-brain barrier permeability**

To evaluate the blood–brain barrier integrity, Evans blue (EB) dye was used as a marker of albumin extravasation [14]. EB was expressed as μg/mg of brain tissue against a standard curve.

**Immunohistochemical technique**

Formaldehyde-fixed tissue was embedded in paraffin wax for further immunohistochemical examination. Sections were deparaffinised in xylene. Antigen retrieval process was performed twice in citrate buffer solution (pH: 6.0), first for 7 min, and second for 5 min, boiled in a microwave oven at 700 W. They were allowed to cool to room temperature for 30 min and washed twice in distilled water for 5 min. Endogenous peroxidase activity was blocked in 0.1% hydrogen peroxide for 20 min. Ultra V block (Cat. No: RB-222-P0) (1:100 dilution), GFAP antibody (1:100 dilution) (Cat. No: PA3-067, Invitrogen, Carlsbad, CA, USA). After TBI, blood samples were taken from the animals and analysed with various biochemical markers. Then, parietal lobe of the brain cortex were rapidly removed. For the histological examination, brain tissues were fixed in 10% formaldehyde solution, post-fixed in 70% alcohol, and embedded in paraffin wax. The sections were stained with haematoxylin-eosin (H&E).

**Statistical analysis**

Statistical analysis of biochemical findings was carried out using GraphPad Prism 4.0 software (GraphPad Software, 2003, San Diego, CA, USA). All data are presented as mean ± standard deviation (SD). Groups of data were compared with an analysis of variance (ANOVA) followed by Tukey’s multiple comparison tests. Values of p < 0.001 and p < 0.01 were considered as statistically significant (Fig. 1). For the statistical analysis of VEGF and GFAP expression, Kruskal-Wallis and Mann-Whitney U non-parametric statistical tests were used in the intergroup comparisons depending on the variables and the results were given as the mean ± SD and mean rank. And, the results were considered statistically significant for p = 0 with Kruskal-Wallis test and p < 0.05 with Mann-Whitney U test (Table 1).
RESULTS

Biochemical findings
The following biochemical parameters were compared between groups (Fig. 1).

Tissue MDA levels
Malondialdehyde values in the trauma (TBI) group were significantly higher than those of the control group (p < 0.001), while the TBI + honokiol group had significantly lower levels than those of the trauma (TBI) group (p < 0.001).

Tissue GSH-Px levels
Glutathione peroxidase levels of the control group were significantly higher than those of the trauma group (p < 0.01), while those of the TBI + honokiol group were also significantly higher than those of the trauma group (p < 0.01).

Tissue MPO activity
Myeloperoxidase levels of the control group were significantly lower than those of the trauma group (p < 0.01), while those of the TBI + honokiol group were also significantly lower than those of the trauma group (p < 0.01).

Evans blue assay for blood-brain barrier permeability
Blood–brain barrier permeability values of the control group were significantly lower than those of

the trauma group ($p < 0.001$), while those of the TBI + honokiol group were also significantly lower than those of the trauma group ($p < 0.001$).

**Histopathologic findings**

When brain cortex of the control group was examined, the pyramidal neurons were polyhedral and had chromatin-rich nuclei. Glial cells were observed with small round nuclei and distributed solitary.

The lumen of the capillary vessels in the cortex was regular and the endothelial cells were flat (Fig. 2a). Histopathological examination of the TBI group revealed some degenerated pyramidal cells, pyknotic nuclei, dilated and congested blood vessels, hyperplasia in endothelial cells, inflammatory cell infiltration around the vein and disruptions in glial extensions (Fig. 2b). In the histopathological examination of the TBI + honokiol group, we observed a decrease in degenerated pyramidal neurons, polygonal and dense-chromatin nuclei, slight dilated blood vessels and flattened endothelial cells towards the lumen and decrease in inflammatory cells around the vessel (Fig. 2c).

**Immunohistochemical findings**

Vascular endothelial growth factor expression in the capillary endothelial and some glial cells in the cortex showed a positive reaction in the control group sections (Fig. 3a). In the TBI group, glial cells around some degenerated neurons, dilated capillary endothelial cells and vascular inflammatory cells showed increased VEGF expression (Fig. 3b). In the TBI + honokiol group, VEGF expression was positive in the endothelial and few inflammatory cells of the mildly dilated blood vessels (Fig. 3c). When GFAP expression was examined in the control group, it was observed that the glial foot processes around the capillary vein covered the basement membrane like a meshwork and were firmly bound to the endothelial cells, and the expression of GFAP protein was significant (Fig. 3d). In the TBI group, loss of glial extensions was observed with deterioration of the glial food processes around the dilated capillary vessels. GFAP positive expression was observed in the short thick extensions away from the vessels (Fig. 3e). A significant increase in GFAP expression was observed in the glial food processes that covered the lumen of regular capillaries in the TBI + honokiol group (Fig. 3f).

**DISCUSSION**

Shortly after TBI, lack of blood flow causes necrotic neuronal death; however, greater loss of apoptotic

neurons may then occur after secondary injury of hypoxia/ischaemia and oxidative stress and inflammation [8, 9, 12].

Previous studies have shown that a variety of pathological factors, such as oxidative stress, the inflammatory response and apoptosis, are involved in secondary brain injury after TBI. Furthermore, early interventions to reduce the level of oxidative stress and the extent of the inflammatory response can significantly reduce the extent of TBI [13]. Baloğlu et al. [2] observed a significant increase in MDA levels in spinal cord injury and a significant decrease in level of GSH and MPO. They have observed degenerative changes in some multipolar and bipolar nerve cells and pyknotic changes in the nucleus of glial cells.

Traumatic brain injury initiates a neuroinflammatory cascade characterised by microglial activation and increased production of proinflammatory cytokines [24]. TBI often promotes disruption of blood–brain barrier integrity and the neurovascular unit, which can result in vascular leakage, oedema, haemorrhage, and hypoxia. Other pathologic mechanisms include cell death within the meninges and brain parenchyma, stretching and tearing of axonal fibres, and disruptions at the junctions between white and grey matter, stemming from rotational forces that cause shearing injuries [3]. In this study, histopathological examination of the TBI group revealed some degenerated pyramidal cells, pyknotic nuclei, dilated and congested blood vessels, hyperplasia in endothelial cells, inflammatory cell infiltration around the vein and disruptions in glial extensions (Fig. 2b).

In the TBI + honokiol group, pyramidal neurons were less degenerated, also there were slight dilatation of blood vessels, improvement of endothelial cells towards the lumen, and reduction of inflammatory cells in the vessel (Fig. 2c). Feng et al. [11] reported that TBI can result in synapse loss or damage and may contribute to observed behavioural, cognitive, and neurological disorders.

Vascular endothelial growth factor is effective on vascular and neural development. It was thought that brain oedema was dominant because of the increase in VEGF expression and blood–brain barrier destruction in the post-traumatic contusion stage [6, 43]. Lenzlinger et al. [23] found that inhibition of VEGF significantly reduced regional cerebral oedema in TBI rats. Krum and Khaibullina [19] showed that inhibition of VEGF signals, including VEGF-R1 receptors, decreased the numbers of reactive astrocytes and prevented glial scar formation in TBI models. In our TBI group, an increase in VEGF expression levels, vascular permeability, and rapid interaction of VEGF receptors in endothelial cells led to the destruction of vascular wall in the blood–brain barrier and the formation of oedema. The neuroprotective function of VEGF is thought to be due to a combination of direct neuroprotective effects and stimulation of angiogenesis. GFAP, a brain-specific protein that acts as the major integral component of the cell skeleton of astrocytes, GFAP after brain injury discharges the brain cells into the interstitial fluid in the environment and causes deterioration in the blood–brain barrier [32]. An increase in GFAP expression is a cardinal feature of many pathological conditions of the central nervous system and astrocytes. Increasing numbers of GFAP positive expression astroglia cells following TBI have been described in several experimental studies in animals. GFAP was positively expressed in the normal brain tissue, processes in astrocytes around blood–brain barrier rupture was defined as significant GFAP expression [15, 50]. Özevren et al. [37] showed that glial food processes around the blood vessels were decreased and GFAP expression was positive after trauma.

Honokiol with its antioxidant effects was shown to provide protection against cerebral ischaemia-reperfusion (I/R) injuries and dermatological disorders [52]. It has been reported that honokiol can provide potential support to clinical trials in ischaemia treatment by passing through the blood–brain barrier in low-dose long-term treatments [48]. Honokiol has been reported to protect the rat brain from focal cerebral ischaemia-reperfusion (I/R) injury by inhibiting neutrophil infiltration and production of reactive oxygen species [28]. In a similar way to our study, they investigated the effects of honokiol, a cell cycle inhibitor, on neuronal damage reduction and functional recovery after TBI in rats. They demonstrated that honokiol, administered intravenously, has a strong neuroprotective effect against sensorimotor and cognitive deficits after TBI, which is highly associated with the survival of increased neurons. It has been suggested that the neurocompatibility mediated by honokiol after TBI may affect the molecular mechanism due to suppression of over-activated cell cycle [47]. Talerek et al. [45] have made a comprehensive assessment of the potential molecular mechanisms of action that are considered as a promising agent in the treatment and management of neurodegenerative
deteriorates along with the increase in inflammation towards endothelial cells. Due to the effect of honokiol, the improvement of vascular wall due to decreased inflammation in this region and the regular distribution of glial food processes define the antioxidative development. Considering the important role of antioxidants and inflammatory responses in cerebral damage induced by traumatic head injury, honokiol is thought to be important in decreasing lipid peroxidation and protecting the membrane structure of blood-brain barrier, degeneration of neurons and glial cells.

REFERENCES

CONCLUSIONS

The neuroprotective effect of honokiol was found to be parallel to the reduction of lipid peroxidation and inhibition of inflammatory cell in cerebral tissue. After trauma, the structure of glial food processes deteriorates along with the increase in inflammation towards endothelial cells. Due to the effect of honokiol, the improvement of vascular wall due to...
