Abstract

Myokines; a group of cytokines mainly small proteins are released by myocytes during muscular contraction and proved to have many biological effects locally or at systemic levels. The main objective was to study the morphological alterations and myokines expression in rat gastrocnemius muscle following forced compared to voluntary muscle contraction. Thirty-six adult male Wistar rats were divided into 3 groups: control, voluntary exercise and forced swimming regimen. The experiment last for 3 weeks. The weight of rats and serum corticosterone levels were recorded. The gastrocnemius muscle samples were processed for histological and immunohistochemical study of different myokines. The mean weight of rats showed no statistical difference between groups. Corticosterone level significantly increased after forced exercise. Voluntary exercise muscle fibers appeared hypertrophied with prominent transverse banding and dominating satellite cells. Forced exercise muscle showed atrophied widely spaced muscle fibers and inflammatory cell infiltrate. Voluntary exercise significantly increased optic density of interleukin 6, macrophage inhibitory and brain derived neurotrophic factors, whereas the forced exercise group showed significant decrease in their optic densities. The optic density of vascular endothelial growth factor significantly decreased in the forced exercise group. Forced exercise could be harmful to the skeletal muscle fibers and it decreases the secretion of important myokines.
Further, forced exercise significantly increases the serum corticosterone level. The use of exercise for the attainment of healthy life style or in psycho or neuro therapy should follow a thoroughly studied program for welfare of human health.

**Key words: forced exercise, voluntary exercise, skeletal muscle, myokines, corticosterone**

**INTRODUCTION**

The emerging knowledge that skeletal muscles have a secretory function has opened an immense and exciting field in the study of muscles. The contracting muscle motivates production and secretion of many cytokines that are called myokines. Though some of these myokines were described as pro-inflammatory cytokines [1,2], myokines are lately branded as potential applicants for treating metabolic and chronic diseases associated with a sedentary life-style [2].

Interleukin 6 (IL-6) is the first cytokine to be identified in the blood stream during muscle contractions. It is produced and released from the skeletal muscles in significant levels after prolonged exercise and produced pleiotropic functions in different tissues of the body [3]. However, contradictory harmful effects of IL-6 as promotion of atrophy and muscle wasting have been proposed [4].

Vascular endothelial growth factor (VEGF) is considered as the utmost important pro-angiogenic cytokine in most tissues including skeletal muscle [5]. It enhances neovascularization, and thus improves tissue oxygenation [2].

The macrophage migration inhibitory factor (MIF) is considered as an inflammatory mediator associated with metabolic diseases and can signal molecular links between adipocytes and myocytes. It has been proposed to have a role in myoblast differentiation but this role is still indistinct [6].

Brain-derived neurotrophic factor (BDNF) is now a well-known neurotrophine that regulates various neuronal processes [7]. It is recently suggested to play a vital role in metabolic regulation of skeletal muscle and in controlling energy homeostasis [8].
The improving effects of voluntary exercise on physical health have been proved [9], but contradictory results are raised about the ideal intensity, duration, and type of exercise required to get the favorable effects and avoid the bad effects of the high intensity exercise on systemic inflammation [2,10]. This study investigated whether the type of physical exercise, voluntary or forced, would induce different morphological changes in the structure of the skeletal muscles, in their myokines immuno-expression and in the serum corticosterone level, aiming to define the right way for the use of exercise as a therapeutic measure in different diseases.

**MATERIAL AND METHODS**

**Experimental animals**

Thirty-six adults male Wistar albino rats weighing 180-230 g were used in this study. The animals were kept under constant environmental and nutritional conditions throughout the study in metal cages (4 rats in each cage) in the behaviour lab (College of Medicine- Taibah University), exposed to a light/dark cycle at 14:10 hour photo cycle at 22-24°C with a free access to food and water and were observed for normal movement for 7 days. The animals were cared for in accordance with the National Institutes of Health guide for the care and use of Laboratory animals (NIH Publications No. 8023) and the protocol was approved by the Faculty Experimental Ethics Committee.

The rats were randomly divided into 3 groups (12 rats each): 1. Control group: were kept on a standard chow diet for 3 weeks. 2. Voluntary exercise group: were allowed to voluntary running (voluntary wheel running) for 3 weeks. 3. Forced exercise group: were kept on a forced swimming regimen for 3 weeks.

**Voluntary exercise (running) regimen**

The rats were housed individually in cages equipped with rat running wheels (Lafayette Instrument Company, Inc. 3700 Sagamore Parkway North Lafayette, IN 47904 USA), and allowed to voluntary running for 3 weeks. The running wheels were tested every other day to confirm their proper function and the mean running distances were recorded for each rat [11].
**Forced exercise (swimming) regimen**

The rats were individually forced to swim inside vertical glass cylinders (60 cm in diameter, 80 cm in depth) with no possibility of escape. The water depth was 50 cm maintained at a 25-28 °C. Swimming was conducted 15 min daily for 21 days. After each session of swimming, the rats were removed, allowed to dry and returned to their cages [12,13]. The distances-swum by each rat were recorded automatically via a computer software (Ethovision XT version 8.0, Noldus Information Technology, Nieuwe Kanaal, 5 Wageningen, The Netherlands).

**Recording the weight and the corticosterone levels**

The weight of each rat was recorded at the beginning of the experiment and before sacrifice.

On sacrifice (at 8 am), blood samples were collected from the thoracic cavity to quantify the serum corticosterone level. The sera was separated and stored at -80°C till the corticosterone levels were assessed by using ELISA kits (ALPCO Diagnostics, Orangeburg, NY, USA) according to the manufacturers’ instructions [14].

**Muscle sample collection and histological preparation**

Twenty-four hours after the last day of the experiment, the animals were sacrificed by cervical dislocation [12], the hind limbs were dissected and the main bulks of the gastrocnemius muscles were removed. Longitudinal section (LS) and transverse sections (TS) samples were prepared from the muscles for paraffin sections, and stained with haematoxylin and eosin (H&E) for light microscopic structural study via Bright field Automated microscope (Olympus BX 36).

Serial paraffin sections (4 μm) were stained using primary polyclonal anti-rat antibodies against the chosen muscle myokines (Uscn Life Science Business Co., Ltd.; polyclonal Rat IL-6 PAA079Ra71, Rat VEGF PAA143Ra71, Rat MIF PAA698Ra01, Rat BDNF PAA011Ra01) and for Proliferating Cell Nuclear Antigen (Ab-1 clone PC 10 mouse monoclonal antibody) to evaluate the proliferating muscle satellite cells [15]. The immunoperoxidase technique with a Bench-Mark instrument (Ventana Company) was used for immunostaining [16].
A light microscopic examination of the immuno-expression was performed and the immunohistochemical staining of myokines was evaluated by measuring the optical densities (ODs) of the stained sections. Briefly, five non-overlapping representative fields were captured at a magnification of ×200 with a microscopic field area of 786.432 m². The ImageJ (NIH) software, version 2.0.0-beta4 (National Institutes of Health, Bethesda, MD, USA) was used for evaluation of the OD of immuno-stained myokines regarding Verghese et al. as follows: deconvolution of the image using DAB vector into three different coloured images, calibration of the brown DAB image by measuring the mean integrated intensities (mean grey value) of five non-overlapping zones of the stained tissue and then the intensity numbers were transformed into the OD using the following equation: \[ \text{OD} = \log\left(\frac{\text{max intensity}}{\text{mean intensity}}\right) \], where the max intensity=250, and the mean intensity=mean grey value [17]. The PCNA stained cells (proliferating cells) were counted in five non overlapping fields (x400) of the stained sections of the different groups for statistical analysis.

Statistical analysis

Statistical analysis was performed using SPSS V.23 (IBM Corporation, Somers, NY, USA). Values are presented as means ± standard error of mean (S.E.M). Statistical evaluation was done using one-way analysis of variance (ANOVA) followed by Bonferroni pairwise comparisons and the level of significance was determined to be less than 0.05 throughout the study. Pearson’s test was used for determining the correlation of distances and the P and r values were recorded.

RESULTS

The weight and corticosterone level

The mean weight of the rats before and after the experiment showed no significant difference between the groups (Table 1).

The corticosterone level showed no significant difference between the control and running groups (\( P = 0.937 \)). Whereas, a highly significant increase in the levels of corticosterone were found between the control and swimming and between running and swimming groups (\( P < 0.001 \)) (Fig. 1).
**The mean distance run or swum by the rats**

The mean distance run by the voluntary running rats was 7253.92 ±935.38 m/day while the mean distance swum by the forced exercise group was 72.67±9.38m/day (Fig. 2). Except for the detected significant correlation between the mean distance run and the OD value of VEGF (r= 0.867, P<0.001), no significant correlation was detected between the means of distance run or distance swum and any of the OD values of all analyzed myokines.

**Histopathological and immunohistochemical analysis**

The control gastrocnemius muscle sections revealed a well-organized bundles of muscle fibers separated by scanty perimysial connective tissue contained thin walled muscular blood vessels. The myofibers showed a well-defined myofibril with peripheral dark stained nuclei, and few lightly stained satellite cells. (Fig. 3 a, b, c).

Sections of voluntary running rats showed bundles of hypertrophied muscle fibers with wide perimysial spaces containing fine collagen fibers. Nearly all the myofibers exhibited slight shearing with prominent transverse unstained banding of Z Lines striation. The lightly stained satellite cells were dominating and can be identified from the dark stained myofiber nuclei. Slightly increased perivascular connective tissue and some venous congestion were observed (Fig. 3 d, e, f).

Sections of forced exercise rats showed a sporadic widely spaced bundles of muscle fibers with marked perimysial fibrosis. The individual fibers appeared atrophied, less in size and widely spaced compared to other groups, whether few fibers appeared hypertrophied. Most fibers lost the normal myofibril appearance and possessed homogenous acidophilic cytoplasm. The muscular blood vessels appeared with thick walls, marked perivascular fibrosis and inflammatory cell infiltrate. There were focal areas of necrosis with cellular infiltration and loss of the normal myofiber striations. The pale satellite cell nuclei are hardly seen (Fig. 3 g, h, i).

IL-6 immuno-stain expression showed marked increase and diffuse distribution in most muscle fibers of the voluntary running group. A marked decrease or absence of
the stain was observed in the forced exercise muscle fibers (as compared to control group) (Fig. 4 a, b, c).

VEGF immuno-stain expression showed irregular distribution of the stain in the voluntary running group, that appeared to be increased in some fibers and markedly decreased in others. Whether, the stain was markedly decreased in nearly most fibers of the forced swimming group (as compared to control group) (Fig. 4 d, e, f).

The MIF immuno-stain expression, though was difficult to identify, but it appeared to be increased in many fibers of the voluntary running group, but markedly decreased in the forced swimming group (Fig. 4 g, h, i).

BDNF immuno-stain expression was clearly identified with marked increase in nearly all muscle fibers and in satellite cells of voluntary running group, and marked decrease in the forced swimming group (Fig. 4 j, k, l).

Voluntary exercise group showed significant increase of mean OD values of L-6, MIF, and BDNF, whereas the forced exercise group showed significant decrease in their values compared to the control group. On the other hand, the OD of VEGF showed a non-significant decrease in the voluntary running group and a significant decrease in the forced exercise group as compared to the control one (Table. 2).

The mean number of PCNA stained satellite cells were significantly higher in voluntary exercise group (5.5±1.31), and significantly lower in the forced exercise group (0.83±0.72) as compared to that of the control group (1.83±0.72) (Fig. 5,6).

**DISCUSSION**

The non-significantly changed mean weight of the animals in both types of exercise was consistent with results of Arnold and Salvatore [18].

The non-significant change of corticosterone levels in the voluntary running group could affirm the non-occurrence of stress after voluntary exercise regimen, whereas its significant increase after forced swimming regimen can support the occurrence of stress and/depression after forced swim exercise [13,19]. This could be
due to the gradual acclimatization to exercise in voluntary running that minimize the acute psychological and physiological stress to which the rats are exposed in acute exposure to exercise [20].

Inconsistent reports exist on the responses of skeletal muscle to different modes of exercise [21]. In this study, we hypothesized that skeletal muscle would react to voluntary exercise as a physiological stimulus increasing the function by hypertrophy, but the forced exercise would be a harmful pathological stimulus. Voluntary wheel running caused hypertrophy of muscle fibers with prominent transverse banding and increased number of activated satellite cells which can denote that voluntary running can represent an appropriate regimen for satellite cells activation, proliferation, and/or differentiation with the resultant increased muscle mass [21].

After the forced swimming regimen, there were atrophy of muscle fibers with focal areas of necrosis, cellular infiltration and decreased number of activated satellite cells. In accordance with the present results, forced exercise adopted by treadmill, caused an immediate localized degenerative effect and late macrophage infiltration and necrosis of the deep slow antigravity muscle fibers [22]. Interestingly, they proved that changing the load laid on the muscle using the same type of exercise can evoke different degenerative muscle effects [22]

That practicing exercise can activate systemic intercellular and inter-organ communication via secreting the cytokines or myokines has raised the importance of studying these factors as therapeutic targets [23]. The significant increase and diffuse distribution of IL-6 immunostaining in the muscle fibers after voluntary running can denote its local production by different types of skeletal muscle fibers and can prove its positive role in the physiology of hypertrophic muscle growth [4]. It is important to consider that the local production of IL-6 in voluntary running muscle fibers might be transient and of short-term action, but it imposes important autocrine benefits either as an anti-inflammatory factor or as a regulator of glucose uptake and energy metabolism [3,13]. This action is different from the action of the long-lasting increased serum IL-6 levels that are associated with inflammatory conditions and accompanied with increased muscle wasting and atrophy [4].
The significantly decreased and irregularly distributed immunostained IL-6 in the forced exercise fibers can display the absence of a local beneficial or harmful effect of IL-6 after the forced exercise regimen. This can be attributed to the rise of endogenous glucocorticoid production due to stress of the forced exercise which can also give explanation for the atrophy detected in groups of muscle fibers [24].

It has been increasingly clear that, in response to exercise, a skeletal muscle sometimes secretes a profuse amounts of angiogenic factors, including VEGF that may function primarily as paracrine factors, but a controversial debate exists over the ideal amount of exercise needed for their beneficial effects [25]. The non-increase of VEGF immunostain after voluntary running observed in this study could be due to non-regular expression in all muscle fibers, as VEGF is expressed only in the predominantly glycolytic fibers. Also, there might be the hypoxia level needed for the generation and regulation of VEGF is not reached during the voluntary running regimen [26,27]. However, the lone significant correlation of the OD of VEGF expression with the mean distance run can prove the increased VEGF expression in the skeletal muscles in voluntary exercise but not in forced exercise.

The significant decrease of VEGF after the forced swimming exercise could be due to the inhibitory effect of stress of the forced regimen and the accompanying raised serum corticosterone level causing inhibition of endogenous VEGF production [24]. This coincided with the observed necrosis in some areas of the skeletal muscles due to the decreased basal skeletal muscle capillarization with the resultant muscle cell apoptosis, and inhibition of angiogenesis during this type of exercise [28].

The study showed significant increase of the immunostain and OD values of both MIF and BDNF in the muscle fibers of the voluntary running rats. This is in accord with the recently proved elevated serum levels of both myokines by voluntary wheel running [13]. The concomitant relation of both myokines could lie in their suggested effects on the myogenic cells as both are expressed in the myoblasts and are modified during myoblast differentiation [6].

The decreased immuno-expression of both MIF and BDNF in the muscle fibers after forced exercise might be due to the psychological stress as denoted by the
increased serum corticosterone level after the swimming regimen. Their decreased levels are consistent with the decreased serum levels of both myokines in forced swim-induced depression [13,29]

CONCLUSIONS

The voluntary and forced exercises have different effects on the structure and myokines expression in skeletal muscle tissue and also on the serum corticosterone level. Forced exercise could be harmful to the muscle fibers and it decreases the its myokines production , whereas voluntary running can increase the muscle mass and progenitor satellite cells. The use of exercise for the attainment of healthy life style or in psycho or neuro therapy should follow a thoroughly studied program for welfare of human health

Conflict of interest

The authors declare that no conflicts of interest for this work. No funding source for the research. The authors carried all the cost of the research

Acknowledgment

The authors express thanks for the technicians of the behavioural lab, College of Medicine, Taibah University, who helped us throughout conduction of the experiment.

Figure 2. The mean distance run by the voluntary exercised rats (a), and the mean distance swum by the forced exercised rats (b).

Figure 3. Digital photomicrographs of sections in the gastrocnemius muscle, (H&E stain), a, d, g x100 and b, c, e, f, h and i x400: 1. Control group (a, b, c) show well organized bundles of muscle fibers (stars) separated by scanty perimysial connective tissue. The myofibers show well defined myofibrils (curved arrows), peripheral dark stained nuclei (thin black arrows) and few lightly stained satellite cells (dotted arrows). A muscular arteriole (A) appear with normal wall thickness. The perimysium around
the bundles contains thin walled blood vessels and scanty fibrous tissue (thick black arrows). 2. Voluntary running group (d, e, f) show bundles of hypertrophied muscle fibers (compared to those of control) (stars) separated by wide perimysial spaces containing fine collagen fibers (thin arrows). Nearly all the myofibers show slight shearing with noticeable myofibrils (thick arrow) and prominent transverse unstained banding of Z Lines striation (white arrows). The lightly stained satellite cells are dominating (dotted arrows) and can be identified from darkly stained myofiber nuclei (curved arrow). Apparent slight increase in perivascular connective tissue (short thick arrows) and slight venous congestion (V) are observed. 3. Swimming group (g, h, i) show widely spaced bundles of muscle fibers (stars) with marked perimysium fibrosis (thin black arrows). Individual fibers looked spaced and small in size compared to other groups. Groups of muscle fibers appear atrophied with apparent small diameter (Thick arrow), but few appeared hypertrophied (short thick arrows). Most fibers lost the normal myofibril appearance and possessed homogenous acidophilic cytoplasm. Muscular blood vessels appear with thick walls, marked perivascular fibrosis and inflammatory cell infiltrate (double arrows). Focal areas of necrosis, loss of normal myofiber striations and cellular infiltration are apparent (white arrows). (a, d, g x 100 & b, c, e, f, h, I x 400)
Figure 4. Digital photomicrographs of gastrocnemius muscle immunostained sections of different myokines in all groups show: 1. marked increase and diffuse expression of IL-6 immunostaining in the voluntary running group muscle fibers, and marked decrease and irregularly distributed expression in the forced exercise fibers (as compared to control sections) (a, b, c). 2. Irregular expression of VEGF stain in the voluntary running group appears to be increased in some fibers and markedly decreased in others) as compared to control). The expression appears markedly decreased in nearly most fibers of the forced swimming group (d, e, f). 3. The MIF exhibit some increase in many fibers of the voluntary running group and marked decrease in the forced swimming group (g, h, i). 4. BDNF immune expression show marked increase
in most muscle fibers and in satellite cells of the voluntary running group and marked decrease or absent in the fibers of the forced swimming group (j, k, l).
