[Received: 7 May 20219; Accepted: 30 November 2019]

Background: Exercise has been shown to be beneficial to the skeleton, in both humans and animals. This study was done to test the sex-related difference in the risk of osteoarthritis (OA) of the knee joint and also on the subchondral bone after moderate running exercise.

Materials and methods: Forty male and female Wistar rats were randomly assigned to four equal groups (2 male and 2 female groups) in the same condition. Ten animals of each sex were selected as control groups, while running exercises were performed in remaining 20 male and female rats, using a motor treadmill to motivate rats to run daily distances of 1 km at 5 days/week within 6 weeks. On day 43, all animals were sacrificed and the knee articular cartilage and also histomorphometric parameters of subchondral bone and mid shaft of tibia were evaluated.

Results: Results showed mild OA in both male and female runner groups. Results in male runner rats were significantly lesser than that in female runners. On the other hand, the difference in female runner group showed significant changes in comparison with other groups in histomorphometric parameters in tibia.

Conclusions: Obtained results showed that the development of knee OA and subchondral bone changes may be related to the sex differences. Although there was no synovitis in male runners, female runner group showed mild hyperaemia dropsy with a moderate synovitis in this region. (Folia Morphol 2021; 80, 1: 127–132)

INTRODUCTION

According to human [7] and animal [12] studies, exercise and mechanical loading are beneficial to the skeleton. Despite the obvious effects of high mechanical loading on the skeleton, the capacity of skeleton to maintain the exercise-induced bone gain remains unknown [27].

Based on multiple studies with experimental models, increased mechanical loading or physical activity triggers bone formation and growth and has positive effects on the skeleton [9, 14, 29]. Studies show that running exercise increases cortical and cancellous tibial bone mass in aged female rats [2].

The articular cartilage health is dependent on the mechanical features of its subchondral bone. It has been shown that bone changes are associated with osteoarthritis (OA) [25]. The architecture of subchondral metaphyseal bone is not uniform. The organisation of trabecular sheets is in a way that they can transfer stress from the overlying layers of articular cartilage, subchondral plate, and calcified cartilage to metaphyseal cortices [15, 18].

In this study, we aimed to evaluate the effects of moderate running exercise on the subchondral bone of tibia in the knee joint, histological assessment and grading of the synovial membrane changes and to conduct a histomorphometric assessment of the mid-shaft of tibia.

**MATERIALS AND METHODS**

All procedures involving the experimental use of animals were approved by the Animal Ethics Committee, a branch of the Research Council of the Veterinary School in Shahid Bahonar University, Kerman Province, Iran.

Forty adult male and female Wistar rats (9–10 weeks of age) with no significant difference in their body weight (251.59 ± 12.31 g) were randomly divided into four equal groups. All rats were allowed a 5-day adaptation period in a room with controlled conditions (temperature 22–25°C and humidity 60–70%) before starting the experiment [28]. Ten animals of each sex were selected as male and female control groups while running exercises were performed in remaining 20 male and female rats for 6 weeks on a motor-driven rodent treadmill (Model T510, DRI Co., Taiyuan, Taiwan), speed of 20 m/min with inclination of 18° for 60 minutes each day on 5 days of every week.

During the exercise period, all animals were fed a standard diet (Javaneh Khorasan Co., Iran).

On day 43, all control and runner rats were sacrificed by overdose injection of pentobarbital sodium (100 mg/100 g body weight, intraperitoneal injection). The body weight was recorded. Then whole of both knee joints were taken and fixed in 10% buffered formaldehyde for 1 day and then was placed in a new solution of 10% buffered formaldehyde for 10 days. Decalcification in 10% formic acid solution was followed by embedding of the complete knee joints in a new solution of 10% buffered formaldehyde for 50 days. 5 μm thickness serial sections were cut with a rotary microtome and mounted on saline-coated slides glass after preparation of histological specimens. Before staining, the sections were deparaffinised in 100% xylene and rehydrated in graded ethanol [1]. The longitudinal sections of the proximal tibia, between medial and lateral intercondyloid spines, and transverse sections of the mid shaft of tibia were cut at 5-μm thickness with a microtome. Histomorphometric measurements of the cancellous bone of the proximal tibia and the cortical bone of the tibial shaft were examined using an Olympus light microscope and photomicrographs were taken by an attached eyepiece camera (Dino-eye, AM-7023, 5Mp, Taiwan) on 40× and 100× magnification. Ten random fields were selected in each slide.

Histomorphometric parameters were described according to the American Society for Bone and Mineral Research nomenclature committee [30]. The histomorphometric parameters evaluated for cancellous bone were bone volume (BV; the percentage of occupied area by calcified bone in relation to the total area), ratio of BV to TV which included trabecular bone volume (BV/TV), trabecular number (TbN; number of trabeculae that a line through a trabecular compartment would hit per millimetre of its length), trabecular thickness (TbTh; the thickness of 40 complete trabecular bone packet on straight, rod-like trabecular structures in each section), osteoblast surface (ObS/BS; per cent of bone surface occupied by osteoblasts and osteoclast surface (OcS/BS; per cent of bone surface occupied by osteoclasts) [17, 30].

The histomorphometric parameters evaluated for tibial shaft were total tissue area (Tt Ar), marrow cavity area (Mc Ar) and cortical bone area (Cb Ar).
parameters were chosen based on a previous study [1]. The results were obtained by using an Olympus light microscope and an attached eyepiece digital lens (Dino-eye, AM-7023, 5Mp, Taiwan).

Statistical analysis
Results were expressed as means ± standard error using the software SPSS 16 (version 16, Chicago, USA). Statistical analysis was carried out using an independent T-test and one-way ANOVA. Also the Tukey’s test was used for post hoc analysis with significance set at p < 0.05.

RESULTS

Weight
In the female exercise group, body weight decreased markedly, compared to the control group at the end of the intervention (Table 1).

Bone histomorphometry and histopathology
Knee joint: Gross findings. The surface of the femoral cartilage was found to be smooth in both female and male control groups, whereas in four male runner rats, the articular surface was irregular after the sixth week. In the female exercise group, superficial cartilage irregularities were detected in the trochlea and femoral condyles.

Histological finding
Our findings were indicative of mild OA in both female and male exercise groups. The results in male runner rats were less significant than those of female runners (Table 2).

Based on the findings, the synovial layer was normal in both female and male control groups. Most male runner rats in the control group had a normal condition. There was no synovitis in male runners. However, the synovial joint seemed almost coarse and thick in the female runner group, with mild hyperaemia dropsy. There was also a moderate synovitis in this group (Table 2).

In the female exercise group, OcS/BS% was found to be significantly lower than that of the female control group (Table 3).
In the female runner group, ObS/BS% showed a significant increase compared to the female controls (Table 3).

The trabecular number (TbN) increased significantly in both female and male exercise groups, compared to the controls. On the other hand, the trabecular thickness (Tt Ar) difference between female runner and control rats was significant (Table 3).

The BV/TV ratio was higher in male and female exercise groups, compared to the corresponding control groups. The difference between female runner rats was significant (Table 3).

A greater total tissue area (Tt Ar) and a smaller marrow cavity area (Mc Ar) were found in both exercise groups, compared to the controls. The difference between the control and runner female groups was significant (Table 3). On the other hand, the cortical bone area (Cb Ar) was significantly greater in the female exercise group in comparison with the corresponding control group (Table 3).

**DISCUSSION**

In the present study, moderate-intensity running was found to damage the articular cartilage; therefore, it is considered a strenuous exercise, especially for females. Based on our findings, in moderate-intensity exercise, women experience more cartilage changes, compared to men with a similar body weight. According to previous research, the cartilage volume of normal men is 33% to 42% larger than that of normal women, as indicated in radiographic analyses [3].

Moreover, Jones et al. [13] showed that the knee cartilage of men is significantly more than that of females. It was concluded that sex differences in cartilage development could explain the variations in OA of the knee in later stages of life. In addition, Faber et al. [6] reported that after adjustments for height and body weight, gender differences did not influence cartilage volume. Nevertheless, it was reported that body and bone size had significant effects on this difference, suggesting a direct relationship between cartilage volume and bone size [5, 13].

Evidence suggests the thicker cartilage of men, compared to women [22]. In contrast, no gender-related effects have been reported after adjustments for body weight and tibial head diameter [4]. Some significant changes were detected in rats with matching age and body weight; therefore, other parameters might explain gender differences

Previous studies show that running exercise decreases fat mass [7, 20]. Our obtained weight results were similar to this study.

The main bone function is to bear gravity-induced mechanical forces and muscle contraction and to facilitate efficient body locomotion [23]. In a study by lwamoto et al. [11], to preserve the positive effects of exercise (for 8 weeks), continuous exercise was found to be necessary. To explain the mechanism through which exercise leads to increased bone mass on histomorphometry, Yeh et al. [31] showed that suppressed bone resorption and improved bone formation might be responsible for the positive effects of exercise on the cancellous bones of tibia in aged female rats. Moreover, Chen et al. [2] showed that exercise leads to cortical bone mass accumulation in the tibia of aged female rats. Our data demonstrated that moderate running exercise resulted in significant increases in both cancellous and cortical bone mass (BV/TV and Ct Ar, respectively) in a weight-bearing long bone, the tibia, in the female rats. The results of OcS/BS and ObS/BS percentage in female rats indicated that the response of cancellous bone to exercise differs according to the magnitude of mechanical loading to the bone. There is a threshold in mechanical loading to the bones when cancellous bone mass increases, with bone formation exceeding bone resorption (Table 3). These findings are consistent with the researchers’ hypothesis [10, 11].

Joint tissues can sustain minimal damage without progressive change. It is known that cumulative micro-damage can lead to bone remodelling, stiffening, and cartilage lesion progression. Peak dynamic forces applied at a high rate cause subchondral bone remodelling and stiffening [8]. In this study, cortical and cancellous bone areas increased significantly in the tibia due to exercise. It should be noted that exercise duration and intensity were probably ideal for increasing cancellous bone mass in our study. Our results also demonstrated that the effect of exercise in females was more significant than males.

In a previous study, it was reported that moderate running exercise significantly increased cortical and cancellous bone mass in tibia [11]; our findings are in consistence with this study. This finding might be attributed to the position of tibia and mechanical loading on the tibia during treadmill running [11, 21]. Moreover, Chang et al. [1] showed that the cancellous bone response to exercise changes relative to the bone mechanical loading. This finding is consistent
with a previous study, which indicated the positive site-specific effect of treadmill exercise on bone mineral density, with predominant weight-bearing sites [11].

CONCLUSIONS

Our results showed the moderate exercises are more harmful in females than males. Also subchondral bone changes in females may be more visible than in males.
