Abstract

Background: Celiac trunk is the first major visceral branch of the abdominal aorta. The aim of this work was to present the celiac trunk division pattern and its anatomical variants in a sample of Polish population.

Materials and methods: Celiac trunk dissection was performed in 50 adult cadavers in the Department of Anatomy, Jagiellonian University Medical College. Cadavers of Polish subjects were included. Cadavers with previous upper abdominal surgery, abdominal trauma, disease process that distorted arterial anatomy or signs of putrefaction were excluded. Celiac trunk variations, accessory vessels, and vertebral level of origin were described. Celiac trunk patterns were reported according to the Adachi classification. This study was reviewed and approved by the local Ethics Committee.

Results: Celiac trunk consisting of the left gastric, common hepatic and splenic artery (type 1 according to the Adachi classification) was found in 82% of cadavers. The true tripod was found in 20% and the false one in 80%. Additional vessels were also found: greater pancreatic from the splenic artery and left inferior phrenic from the left gastric artery, which accounted for 2% sections. Type 2 according to the Adachi classification (i.e. the hepatosplenic trunk) were found in 16% of the sections. Other types of celiac trunk were not observed. The level of origin was found to be at the inter-vertebral disc between T12 and L1 in all of the cases.

Conclusions: Based on the analysis of the sectional material of the Department of Anatomy, it was found that the typical visceral segmental division is approximate to that observed by Adachi in its classification, whereas the second type of celiac trunk was twice as frequent and no other, less frequent were found. variety.

Key words: tripod, anatomical variations, Adachi classification, celiac trunk
INTRODUCTION

The celiac trunk (CT) is the first anterior visceral branch of the abdominal aorta (AA) and it arises from AA immediately below the aortic hiatus at the level of T12-L1 vertebra. It measures approximately 1.5-2 cm. It runs down, right and slightly forward, lying back from the lesser omentum. Its ending lies just above the upper border of the pancreas. CT is surrounded by the celiac plexus. It was first described by Albrecht von Haller in 1756 [1], as “tripus Halleri”, which represents the classical type of branching, known as trifurcation in the left gastric artery (LGA), common hepatic artery (CHA) and splenic artery (SA). Anatomic variation of CT has been first classified by Adachi in 1928, based on 252 dissections of Japanese cadavers, where six types of divisions were described [2] [Fig. 1]. However, two forms of trifurcation have been most commonly observed: a “true” tripod is considered when the CHA, LGA and SA have a common origin, constituting a hepatogastrosplenic trunk. When one of these arteries arises before the remaining two in the course of the celiac trunk, it is called a false tripod [3]. CT supplies the structures derived from the foregut (liver, pancreas, abdominal part of the esophagus, stomach and proximal duodenum). Surgery of the abdominal cavity requires an excellent knowledge of anatomical variations of the celiac trunk. Familiarity with the vascular supply of abdominal organs such as liver or pancreas is basic for numerous procedures (chemo-embolization, liver resection, pancreatectomy) [4]. In the present modern era of imaging techniques, the cadaver still stands as an important and reliable mode of anatomical study [5, 6]. Hence, the aim of this cadaveric study was to analyze and report the vascular patterns of celiac trunk for the first time in a sample of Polish population according to the classification by Adachi.

MATERIALS AND METHODS

Dissection of the celiac trunk was performed in 50 formalin-fixed abdomen specimens in the Department of Anatomy, Jagiellonian University Medical College. The inclusion criteria were: cadavers of Polish nationality subjects. The sex and age was not taken into account. Cadavers with previous upper abdominal surgery, abdominal trauma, disease process that distorted the arterial anatomy or signs of putrefaction were excluded. This study was reviewed and approved by the local Ethics Committee /nr 1072.6120.78.2019/. Informed consent was not required. After dissection of the anterior abdominal wall, and entering the peritoneal cavity, the greater omentum of the stomach was dissected from the transverse
colon, exposing the posterior wall of the stomach and opening the lesser sac. The pylorus was freed from adjacent connective tissue, and the omentum minus was opened along the minor curvature. Once the common hepatic artery, the left gastric artery and the splenic artery were identified, their course was followed to their site of origin. The presence of a “true tripod” or a “false tripod” was examined. Celiac trunk variations, accessory vessels and site of origin were recorded and referred to Adachi’s classification. Care was taken not to overlook a left hepatic artery. The left gastric artery was exposed as well as the coronary vein. The pancreas was also dissected to expose the origin of the superior mesenteric artery (SMA). The vertebral level of the celiac trunk origin was determined by palpation in cephalic direction beginning from the fifth lumbar vertebral body. The structures of the AA, its branches and variations were photographed using a digital camera.

RESULTS

During routine dissection of abdomen we observed the following branching patterns of celiac trunk. CT derived in a common hepatic artery, a left gastric artery and a splenic artery in 82% of the cadavers (41/50). This pattern corresponds to Adachi type I. Furthermore, two different trifurcation patterns were observed; a classical or „true” tripod called “tripus Halleri” and a non-classical type. In the classical type, CHA, SA and LGA were found to arise from the celiac trunk. This was found in 20% of dissections (8/41) (Fig. 2 and 3). In the non-classical type also known as „false” tripod the origin of LGA was located relatively proximal, between the abdominal aorta and the bifurcation of CT, in 33 out of the 41 cadavers (80%) (Fig. 4 and 5). Bifurcation of the celiac trunk (Adachi type II) was found in 16% of the cadaveric dissections (8/50). The celiac trunk divided into CHA and SA (hepatosplenic trunk) whereas LGA originated directly from the abdominal aorta (Fig. 6). In one case, an accessory left inferior phrenic artery was found, rising from the LGA. The given variability was observed in 2%, which corresponds to 1/50 of cadavers. In addition, our attention was drawn by false tripod with two additional arteries: namely the left inferior phrenic artery from LGA and the greater pancreatic artery from SA. Such a variation occurred in 2% (1/50 of cadavers). The variations found in the present study in comparison to other cadaveric studies were summarized in the Table 1. Considering the prevalence of using the computed tomography angiography (CTA) in analyzing anatomical variations, we also compared our results with the radiological studies in Polish population (Table 2). Correlation between gender and celiac trunk variation is given in the Table 3. The level of CT origin was found to be at the inter-
vertebral disc between T12 and L1 in all of the cases. Level of origin celiac trunk in different variations presented in the Table 4.

**DISCUSSION**

Anatomic variations of CT has been described by many authors in various classifications i.e. Rossi and Cova (1904), Lariche and Villemin (1907), Descomps (1910), Picquand (1910), de Rio Branco (1912), Lipschutz (1917), Eaton (1917), Adachi (1928), Tsukamoto (1929), Imakoshi (1949), Michels (1955), Kozhevnkova (1977), Katsume et al. (1978), Vandamme and Bonte (1985), Nelson et al. (1988), Kaneko (1990), Shoumura et al. (1991), Ambica Wadhwa (2011), Panagouli (2013), Olewnik (2016) [2, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21]. In our study we referred to Adachi and Michels who have classified the celiac trunk into six different types [2, 12]. However, these classifications do not include all observed variants of the celiac trunk as well as accessory or replaced hepatic arteries, both of them are still being mentioned and compared with newly described ones [5, 20, 22, 23, 24, 25, 26]. Furthermore, Adachi’s and Michel’s classifications described in textbooks were recently considered to create a scheme of the most frequent variants of the celiac trunk and anatomy of the hepatic circulation [19, 24]. Michel’s classification was also used for depiction of CT and CHA variations in children [27]. Favelier et al. mentioned that this classification provides the best anatomical approach [28]. The types of celiac trunk according to Michels' classification are as follows: Type 1: normal branching; Type 2: hepatosplenic trunk and left gastric artery from aorta; Type 3: hepatosplenomesentric trunk and left gastric from aorta; Type 4: hepatogastric trunk and splenic artery from superior mesenteric artery; Type 5: splenogastric type; splenic and left gastric from the coeliac trunk and common hepatic artery from superior mesenteric artery; and Type 6: celiacomesentric trunk; splenic, left gastric, common hepatic and superior mesenteric arteries arise from a common trunk [12, 21]. Indeed, the most prevalent is type 1, which occurs in 86% of the population [1]. We observed this type in 83.33% of cadavers. Type 2 occurring in 8% of population, was found in our study in 16.67% of cases. We did not observe other less common types i.e. type 3 (hepatosplenovisceral trunk), type 4 (visceromesenteric trunk), type 5 (hepatomesenteric trunk), type 6 (gastrospenlic trunk). Absence of the celiac trunk is the most infrequent variation, with a mean prevalence of 0.38%. In many studies, no celiac trunk absence has been found [4, 10, 19, 29]. In our study, no case of absence of celiac trunk was found (Tab. 1). It is important to notice that Olewnik et al. revealed a shedload of celiac trunk variations non-classified by Adachi (27%) such as: 1) quadrifurcation – normal trifurcation +
accessory hepatic artery – 7.5%; 2) coeliacophrenic trunk – normal trifurcation + left inferior phrenic artery – 12.5%; 3) trifurcation – hepatosplenic artery + accessory hepatic artery – 5.0%; 4) absence of the celiac trunk – 2.5% [11], so we compared our results with other cadaveric studies of the non-Polish populations (Tab. 1).

Kornafel et al. studied the variations of the main branches of the abdominal aorta including celiac trunk and superior mesenteric artery using CTA and 64-detector CT scanner in 201 patients [30]. The authors did not base on the Adachi’s or Michels’ classification and observed 95.5% cases of the normal trifurcation. Other variations observed were hepatosplenic trunk (1.5%), celiacomesenteric trunk (1.5%) and the gastrosplenic trunk (0.5%) [30]. Torres et al. also analyzed variations of the celiac trunk using multidetector computed tomography according to the Uflacker’s classification. In this study the most common trifurcation was observed in 1455/1569 cases (92.7%), the other variants were: gastrosplenic trunk in 64/1569 cases (4.1%) and hepatosplenic trunk in 34 cases (2.2%). Coeliac-mesenteric trunk (8/1569; 0.5%), hepatogastric trunk (4/1569; 0.2%) were rarely observed. In 2 cases the absence of the celiac trunk was noted (0.1%). The hepatosplenomesenteric trunk and the coeliaco-colic trunk were not detected [26]. Kurcz et al. presented results of the another study on 240 patients. The most common patterns were: trifurcation (87.5%), hepatosplenic trunk (8.33%) and gastrosplenic trunk (3.33%). In 1 case celiac trunk was absent (0.42%) and hepatogastric trunk was observed in 0.42% [31]. We compared our results on cadavers with radiologic studies [Table 2].

Due to high number of articles describing variations of the celiac trunk, there was a necessity to find appropriate results evaluated in one review. Santos et al. and Whitley et al. presented results of the previous studies about the celiac trunk and their findings were used to elaborate and compare our results with the other studies focused on the Polish population or the cadaveric studies [32, 33].

Anson et al. showed in cadaveric studies that almost 75% of cases had CT origin at the level of inter-vertebral disc between T12 and L1 [29]. In our study, the site of origin was also found to be at the abovementioned level in most of the cases which does not differs from the population norm.

The most common additional branches of the celiac trunk are single or double inferior phrenic arteries, which were described in 40% of cases in the study by Loukas et al. [34]. In our study, additional vessels were found in 2.77% of cadavers. In one autopsy specimen, the inferior phrenic artery arising from LGA and greater pancreatic artery arising from SA were found. In angio-CT scans Srivastava et al. revealed visceral trifurcation in 28%, bifurcation in
8%, tetrafurcation in 36%, penta-furcation in 20%, hexafurcation in 4%, while in 4% of cases visceral trunk was absent [35].

Anatomical variations of the celiac trunk are secondary to the embryonic developmental changes in the ventral segmental arteries [36]. Primitive segmental branches arise from the dorsal aorta and form the celiac trunk and the superior mesenteric artery. These branches are connected to the ventral longitudinal anastomotic channel. Retention or disappearance of parts of this primitive arterial plexus will give rise to variations of the celiac trunk and the superior mesenteric artery [37].

In studies carried out by Venieratos et al. and Chen et al. no differences were found between genders [19, 38]. However, the occurrence of different types of celiac trunk can be influenced by ethnicity [20]. Our study was carried out on the cadavers of Polish nationality presenting a trifurcated celiac trunk, either a common origin or with one of the three arteries arising first. This incidence is higher than those observed in Korean (10.9%), Caucasian (8.6%), Japanese (10.7%), Indian (30%) and Afro-American population (39%) [3].

Detailed knowledge of normal CT anatomy and its variations is very important during surgery like pancreaticoduodenectomy, liver transplant as well as hepatic artery infusion chemotherapy. Preoperative imaging can help better preparation and planning by the surgical team. But all arterial variations may not be detected in preoperative imaging (only up to 60%–80% of cases). If detected it can help the surgeons to identify the artery and prevent its injury during surgery and post-operative complications like bleeding and ischemia [37]. Currently, arterial variations can also be predicted by the intrauterine ultrasonography examination and observations of the fetus’ intestine position in the following stages of the fetal development [6]. The another modified ultrasonography examination – the 3-D contrast-enhanced ultrasonography could be used in precisely non-invasive diagnosing the celiac artery compression syndrome (CACS) [39]. The patologies of CT and SMA also could be detected by using new technique of the non-contrast MR angiography [33].

Hepatic artery variations, such as anomalous right hepatic artery crossing posterior to the portal vein, are frequently seen (13%). These patients, when undergoing pancreaticoduodenectomy, may require a change in the surgical approach to achieve an adequate resection. Preoperative imaging can clearly identify such variations and help to achieve a safer pancreatic head dissection with proper surgical planning [40]. In transarterial chemoembolisation (TACE) or radioembolisation of hepatic cancers and metastases it is essential to analyze hepatic and extrahepatic perfusion in order to prevent iatrogenic postprocedural complications such as radiation induced ulcers in the stomach and duodenum.
or severe pancreatitis [41, 42, 43]. The variations of the celiac trunk are also significant during TACE in therapy of the pancreas cancer (especially the variations of the common hepatic artery) [44]. Anatomical variations of the celiac trunk are also significant to know in planning the bariatric procedures such as LGA embolisation or the sleeve gastrectomy [45, 46].

CONCLUSIONS

Celiac trunk variations are not uncommon findings, with different anatomic variants being reported. The classical visceral trifurcation was found in Polish population with a comparable frequency, as described by Adachi. Only a low percentage of cases with additional vessels was found. Thus, the importance of knowing the possible variations of this structure is emphasized, which may have implications for surgical interventions and imaging studies related to the abdominal region.
