Abstract

The Southern Karaman sheep, which is very fertile in terms of meat and milk production and is often preferred in livestock raising, is known as a domestic sheep breed. The Hasak sheep is a breed formed by the triple crossbreeding of the German Black-headed, Hampshire and Akkaraman breeds. Arterial feeding of the forelimb is provided by arteria axillaris, a continuation of arteria subclavia. In this study, it was aimed to examine the forelimb arteries in Southern Karaman and Hasak sheep breeds. Totally 8 Southern Karaman and 8 Hasak sheep were obtained from Konya Bahri Dagdas International Agricultural Institute. The sheep were anesthetized with xylazine and ketamine and extravasated by cutting the arteria carotis communis in the neck area of the sheep. The forelimbs of the sheep separated from the body were fixed in 10% formaldehyde solution and then dissections were made and the course and branching of the arteries were examined. It was determined that the arteria brachialis was divided into two main branches as distal arteria brachialis and proximal arteria subscapularis at the
articulatio humeri level of the arteria axillary. Arteria mediana, which is a continuation of arteria brachialis, was also examined in different parts of antebrachium and ended by splitting into branches. According to the findings of the Southern Karaman and Hasak sheep breeds, it was determined that the forelimb arteries had some anatomical differences but were similar in structure to many sheep breeds.

**Key words: arteria, axillaris, brachialis, subscapularis, fore limb, sheep**

**INTRODUCTION**

The Southern Karaman sheep is described as a separate breed formed as a result of the crossbreeding of the Karagül male sheep with the Akkaraman and Dağlıç sheep brought by the Yörüks (Türkmens) who migrated from Turkistan to the Mediterranean during the Ottoman period. The Southern Karaman sheep is very productive in terms of meat and milk and it is often preferred in livestock breeding (11,13). The Hasak sheep is a breed formed by the triple crossbreeding of the German Black-headed, Hampshire and Akkaraman breeds at the Konya Bahri Dagdas International Agricultural Institute. (11,19,21).

In ruminants, the arterial feeding of the forelimb is provided by the arteria axillaris, a continuation of the arteria subclavia, the branch of truncus brachiocephalicus that emerges from the arcus aorta (7,15). The arteria subclavia dexter et sinister originate from the chest cavity and after their passage to the forelimb, the section up to the musculus teres major beam is referred to as the arteria axillaris. Arteria axillaris is divided into two main branches, proximal and distal, at the level of articulatio humeri. On the musculus subscapularis of arteria axillaris, the thickest of the branches that travel proximal along the margo caudalis of the scapula and emerge from arteria axillaris are referred to as arteria subscapularis. The distal part of arteria axillaris from the chorda of musculus teres major to collum radii is called arteria brachialis (4,6). The distal part of arteria brachialis after collum radii is named to as arteria mediana. (3,10,12,15). The branches of arteria subscapularis are arteria thoracodorsalis, arteria circumflexa humeri caudalis and arteria circumflexa scapula. In addition to these branches, many rami
vessels. The aim of this study was to examine the morphological structure of the forelimb arteries in the Southern Karaman and Hasak sheep.

MATERIAL AND METHODS

Totally 8 Southern Karaman and 8 Hasak sheep used in this study were obtained from Konya Bahri Dagdas International Agriculture Institute. The sheep were anesthetized with xylazine HCl (0.2 mg/kg/IV) and ketamine HCl (2.2 mg/kg/IV) and extravasated by cutting the arteria carotis communis in the neck area of the sheep. Then, the body cavity along the median line was opened and the internal organs were removed. Latex, which is described as the raw material of rubber mixed with red dye, was given into arteria axillaris with injectors of various sizes depending on vessel diameter and then left in 10% formaldehyde solution for fixation for 72 hours after applying latex injection method. Then the forelimb arteries were examined individually and their anatomical structures, routes and branches were examined and each photographed separately. Nomina Anatomica Veterinaria was based on the naming of the vessels.

RESULTS

In both breeds studied, arteria axillaris was identified at the level of articulatio humeri to divide into two main branches, namely arteria brachialis, which ran along the limb distally in the triangular area between musculus subscapularis and musculus teres major, and arteria subscapularis, which ran towards the scapula in the caudodorsal direction. The branches of arteria subscapularis which ran along the margo caudalis of the scapula were arteria circumflexa humeri caudalis, arteria thoracodorsalis, r. tricipitis and arteria circumflexa scapula (Fig. 1a,b). The first branch of the arteria subscapularis, which progressed in proximal, was identifyed as arteria circumflexa humericaudalis, arteria...
which gave it towards the front of the limb. It was determined that arteria circumflexa humeri caudalis navigated between musculus brachialis and musculus triceps brachii immediately after its origin. The second branch of arteria subscapularis was arteria thoracodorsalis. This branch originated from the same place as arteria circumflexa humeri caudalis, moving in different directions and within one centimeter proximal of the beginning of arteria brachialis and in the caudal direction. It was determined to progress between musculus latissimus dorsi and musculus teres major. Later, numbers of arteria subscapularis were found to give thin muscular branches in the cranial direction, with 3 in the Southern Karaman Sheep and 2 in the Hasak sheep. After giving the second of these branches in the Southern Karaman sheep and the first in the Hasak sheep, it was determined that the ramus tricipitis originated to feed musculus triceps brachii in the same direction as arteria thoracodorsalis towards the caudal. The continuation of arteria subscapularis, it was seen that it gave arteria circumflexa scapula, which headed to the laterale, moving along the scapula's margo cranialis to feed musculus supraspinatus and musculus subscapularis (Fig. 1a,b).

In arteria brachialis, arteria circumflexa humeri cranialis, arteria profunda brachii, arteria collateralis ulnaris, arteria bicipitalis, arteria transversa cubiti, arteria interosseous communis branches were found to originate and continue to distale as arteria mediana. It was observed that the first branch separated from the arteria brachialis was the arteria circumflexa humeri cranialis in order to feed the musculus biceps brachii. It was determined that this branch was moving towards the cranio-lateral of the limb. It was determined that arteria brachialis gave arteria profunda brachii on the distal part of tuberositas teres major (Fig. 1c,d,e,f,g,h). After giving this branch, it was seen that arteria brachialis gave thin muscular branches which continued in the same direction as it. It was later determined that the branches of arteria collateralis ulnaris, which were aligned but in different directions, and headed caudal, and arteria bicipitalis, which headed cranial, had originated. Arteria collateralis ulnaris followed the exit at the level of epicondylus medialis of humerus and followed along the distal edge of musculus triceps brachii. It was determined that arteria bicipitalis was dispersed in musculus biceps brachii to feed it. Arteria brachialis was observed to give arteria transversa cubiti at the level of articulatio cubiti. Arteria brachialis gave its last branch, arteria interossea communis, at the level of the spatium interosseum antebrachii.
proximalis, then continued as the arteria mediana, cruising along the distal of the limb (Fig 1e,f,g,h).

**DISCUSSION**

In mammals (6), it was reported that arteria axillaris was a continuation of the arteria subclavian and that arterial vascularization of the forearm was provided by this vessel (17). Arteria axillaris was found at the level of articulatio humeri (4). It was found that it continued towards the scapula with the name arteria subscapularis and arteria brachialis, which ran along the distal of the limb. Our study findings were similar to this information.

Arteria circumflexa humeri caudalis had been reported to originate from arteria subscapularis (15,16) and originate from the same place as arteria thoracodorsalis in ruminant (20).

Our results were similar to those of the literature. Similar to our findings, previous studies (6,14,15,16,17) were reported that arteria thoracodorsalis originated from arteria subscapularis with the origin of arteria circumflexa humeri caudalis. However, unlike our findings, other previous study was reported that arteria thoracodorsalis originated from the dorsal wall of arteria axillaris (5).

Similar to our study, the arteria subscapularis continued its path as arteria circumflexa scapula after giving arteria thoracodorsalis, it was also determined by Dursun (4) and Nickel (14).

It was reported that arterial brachialis was the continuation of arteria axillaris, it was named as arteria mediana (5,10) after separation of arteria interosseous communis in proximal of the radius and by Nur and Ari (17) it gave arteria interosseous cranialis instead of arteria interosseous communis by arteria brachialis.

It has been determined our findings differed from those of Nur and Ari (17), and showed similarities with other literature (5,10).

Arteria circumflexa humeri cranialis at the proximal level of the humerus was reported to originate from the axial arteries of the medial face (6). In addition, Nickel (14) reported that arteria circumflexa humeri cranialis originated from arteria brachialis.
Our study findings were in line with the findings of Nickel (14), while they differ from those of Dursun (6).

According to Nur et al (16) and Getty (10), arteria profunda brachii originated from arteria brachialis and according to Dursun (6) it was the first branch of arteria brachialis. Our study findings were similar to those in the literature, but differently, it was not the first branch of the arteria brachialis, but the second branch from the arteria brachialis that emerged after the arterial circumflexa humeri cranialis.

Similar to our study findings, it was reported that arteria collateralis ulnaris was a branch emerging from arteria brachialis and that it was distributed to musculus triceps brachii and arteria bicipitalis was distributed to musculus biceps brachii. (4,5,17).

In contrast to our study findings, Nur and Ari (17) reported that the presence of arteria inertosseus communis was not detected, while Dursun (4) reported that arteria interosseous communis originated from arteria brachialis at the level of spatium interosseum antebrachii proximalis. Our study findings were similar to Dursun (6).

CONCLUSIONS

According to the findings, it was determined that the forelimb arteries in Southern Karaman and Hasak sheep breeds were similar in structure to many mammal and sheep breeds, in addition to some anatomical findings will contribute to the scientific studies to be carried out in this direction and to the literature on the subject.
