Abstract

Muscular and neurovascular variations in the upper extremity are of utmost clinical significance. Here we report a unique bilateral accessory muscle in the forearm and palm of an 89-year-old male cadaver. The accessory muscle presented two bellies on the right side, one in the forearm, innervated by the anterior interosseous nerve, and the other in the palm, innervated by a branch of the median nerve. A long tendon interconnected the two bellies. On the left side, the muscle had a single belly in the palm, which began at the end of a long tendon that extended from the forearm. However, on both sides, the muscle originated from the posterior surface of the flexor
digitorum superficialis belly and inserted along with the first lumbrical muscle into the
dorsal digital expansion of the index finger. The proximal parts of the variant muscles
were sandwiched between the flexor digitorum muscles. The palmar bellies coursed
distally through the carpal canal and lay deep to the superficial palmar arch, and
superficial to the first lumbrical, between the thenar muscles and the lateral-most tendon
of the flexor digitorum superficialis. Arguably, the accessory muscle might be a variant
of a lumbrical muscle, as reported before, but innervation of the proximal belly by the
anterior interosseous nerve suggests that the muscle may well be a deep accessory
muscle at the forearm, probably appeared as a diverted part of the flexor digitorum
profundus. Its space-occupying course through the forearm and palm, especially through
the carpal canal, might be clinically significant as it might contribute to nerve
compression pathologies in the upper extremity. This accessory muscle also indicates
the complex nature of individual muscle formation and evolution of the upper extremity
with constant changes in the morphology of muscles based on their changing functions.

**Key words:** anatomical variations, accessory muscle, first lumbrical muscle,
forearm, flexor digitorum superficialis muscle, median nerve

**INTRODUCTION**

Accessory muscles of the flexor compartment of the forearm are not uncommon,
and when present, they may cause nerve compression syndromes or simulate soft tissue
tumours [4]. Numerous variations of flexor digitorum superficialis (FDS) have been
reported in literature, often consisting of one or more accessory bellies associated with a
varying number of tendons. They were categorised into five classes by Elliot et al
depending on their location and attachments [6]. They may remain confined to the
forearm [3, 23, 25] or extend for varying distances in the palm [11, 13, 19, 21]. Such
anomalies of FDS or its tendons, especially to the index finger, presenting as masses or
pseudo-tumours within the palm, have gained importance in recent years due to the
clinical problems caused by them that require surgery.[6, 21]. Of these, one that bears
slight resemblance to the present case only by virtue of its ‘digastricism’ is that reported
by Caetano et al [2]; it was, however, a small variant confined purely to the forearm,
being placed close to the FDS and inserting rather unusually, into the medial epicondyle
of the humerus. Abundant literature also exists documenting different types of variant lumbricals, especially the lateral two [12, 14, 15, 24]. Rarer variations, such as those associated with flexor carpi ulnaris (FCU) [4, 18] and flexor pollicis longus (FPL) [8] have also been reported.

We report a unique bilateral case of a supernumerary muscle spanning remarkable portion of both forearm and palm, originating from FDS and sharing a common insertion with the first lumbrical into the dorsal digital expansion of the index finger. Innervation of the proximal belly of the right aberrant muscle by the anterior interosseous nerve and its antebrachial origin proximal to the flexor retinaculum suggest that the present case does not fit into either of the two commonest muscular variations of the upper limb. In fact, the palmar bellies of both the muscles by virtue of their location and innervation, are suggestive of an atavistic trait seen normally in amphibians [24].

**CASE DESCRIPTION**

During routine dissection of upper extremities at our medical school, a distinct bilateral variation was noted in the forearms of a male cadaver aged 89 years. A digastric muscle was observed on the right side, consisting of proximal and distal bellies connected by a long tendon (Fig. 1. A, C). The proximal belly, about 7.5 cm long, took origin from the posterior surface of FDS by a short tendon, and then continued in the forearm as a long tendon of 12 cm length. On reaching the wrist, the tendon transformed into a slightly longer distal belly about 8 cm, which entered the palm through the carpal canal on the radial side of FDS tendon for the index finger and was inserted by a short tendon with the first lumbrical to the radial side of the dorsal digital expansion of the extensor tendon of the index finger (Fig. 1. A, C). On the left side, the accessory muscle took origin from the middle of the length of the fleshy belly of FDS muscle by a thin tendon, about 8 cm long, which continued distally as a fusiform muscle belly, 7 cm in length, traversing the carpal canal, and joining the first lumbrical in a common insertion similar to its counterpart on the right (Fig. 2.A, B).

On both sides, the original FDS and flexor digitorum profundus (FDP) tendons for the index finger had normal insertion. The proximal belly of the right accessory
muscle was innervated by a branch of the anterior interosseous nerve (Fig. 1. B). The innervation of palmar bellies on both sides was by the median nerve.

The proximal belly of the muscle on the right side and the tendons on both sides were superficial to the FDP and deep to the FDS. The FPL formed the lateral relation of the proximal parts in both forearms. On both palms, the palmar belly passed through the carpal tunnel and more distally, lay deep to the superficial palmar arch and immediately superficial to the first lumbrical, with which it shared a common insertion. The tendon of the FDS to the index finger was medial to the muscle throughout its course.

**DISCUSSION**

Variant morphology of FDS has been listed by Bergman et al. [1] and reported by several others [5,11], but an accessory muscle belly taking origin from the dorsal surface of the FDS and inserting with the first lumbrical, though does find mention in literature, is rare [9, 10]. Elliot et al. [6] had classified FDS into five types (I-V), based on variations reported between 1866 and 1999. Though the variant described in the present case share some similarities with types III and IV described by him, it is a separate accessory muscle present bilaterally, with origin from the FDS, but insertion independent of FDS tendon for the index finger.

Though the concept of atavism is no longer considered relevant, the fact that the same anomalies recur regularly is difficult to explain as purely by chance [2]. The palmar bellies reported in this case closely resemble the unilateral variant reported by Wesser et al. [24] both by virtue of their location and innervation, but they may well be atavistic structures representing intrinsic flexors of the hand seen in amphibians and most reptiles, where forearm flexors act on the wrist, never inserting distal to metacarpals [6]. Their digits are flexed by superficial and deep groups of intrinsic flexors in the palm. The mammalian musculature appears to have evolved by the forearm muscle bellies retreating proximally from the carpus, while their insertions became parts of long flexor tendons passing through the carpal canal into the palm. The superficial short muscles either disappeared or became parts of superficialis tendons in the palm, while lumbricals developed from the central part of the deep short flexor muscles [2, 3]. Some authors project accessory muscle bellies observed in the forearm attached to the FDS to be anomalous lumbrical muscles with abnormally proximal
origins [12, 15, 22]. Koizumi reported a case of a bilateral anomalous muscle quite similar to this case [12]. The author performed nerve tracing analysis and concluded that the aberrant muscles have a close relationship to the first lumbrical muscle owing to similar innervation. Subsequently, many authors who reported similar findings also quoted the same hypothesis [22].

The FDP and pronator quadratus are believed to represent the deeper layer of forearm muscles of amphibians [6, 10]. In the present case, the proximal belly of the right variant, however, was remarkably distant from the palm and gained innervation from the anterior interosseous nerve. It is, therefore, quite unlikely to be an accessory lumbrical, but could rather be a remnant of the primitive deep group of forearm muscles which gained attachment to FDS. Alternatively, it could be part of FDP which did not fuse with the main muscle during Phase 3 of muscle ontogenesis, when muscle primordia from different layers fuse to form a single muscle, or it could be part of muscle primordia that normally disappear, but persisted and, later differentiated into an accessory belly [3, 4, 5, 7]. The former explanation is more likely as suggested by its innervation. The palmar bellies of the variants could be remnants of the deep group of palmar intrinsic muscles, which perhaps became attached to a separated part of FDP tendon.

Analysis of anatomical variations can contribute to obtaining an actual, not idealized image of the inside of the human body, which is of crucial importance in everyday clinical practice [26]. Accessory or variant muscles of the forearm and palm are of interest to clinicians. They often appear as abnormal swellings, especially palmar bellies commonly manifesting as painful or painless masses [6, 9, 19], that may be misdiagnosed as lipomas, ganglia, vascular malformations, or tendon sheath tumours [13, 21].

In many studies, anatomical variations of the upper limb correlate with nerve entrapment and such compressions are frequently attributed to some type of accessory muscle [16]. Hence it is important to know the normal anatomy and the possible variations of the structures concerned so as to avoid non-specific differential diagnosis of such conditions [16]. Carpal tunnel syndrome is the most common peripheral nerve entrapment encountered worldwide [17]. Although etiology of carpal tunnel syndrome
can vary, ranging from muscle hypertrophy [17] to persistent median artery [17, 20], when forming a content of the carpal tunnel or Guyon’s canal, the supernumerary muscles like the ones reported here, are likely to cause compression of neurovascular structures, most commonly, the median or ulnar nerves [9]. According to Elliot et al. [6] symptoms of nerve compression could be intermittent, manifesting only during proper flexion, when muscle bellies move proximally. The possibility of an aberrant muscle belly should be considered when any abnormal mass detected is soft, in line with a digit, or when it shows increased firmness on active contraction against resistance [9]. Diagnosis of such conditions necessitates confirmation through electrophysiological testing and/or imaging techniques to decide whether or not more invasive surgical intervention is required [17]. While radiographs are of little value in such diagnosis, MRI scanning proves to be of greater use in addition to thorough history and physical examination [21]. Ultrasonography is another useful and more affordable option that has the added advantage of capturing movements of potential aberrant muscles [21]. The palmar bellies reported here were considerably long, traversing the entire span of the carpal canal but as to whether symptoms of nerve compression were present in the person concerned could not be ascertained, as this was an incidental finding observed during dissection, with no clinical history available.

This is a unique case of bilateral variant musculature of upper extremity. Not only does it add a new facet to the evolutionary pattern of limb musculature but also warrants diligent investigation of such unprecedented variations for accurate diagnosis and suitable therapy in case of clinical conditions involving them. The need for surgical excision will depend on diagnosis and symptoms.
