ABSTRACT

Renal vascularization is classically described as a renal artery and vein. However, this vascular pattern presents numerous anatomical variations in terms of their number, origin and course due to ontogenetic alterations.

The aim was to carry out a descriptive study of the renal vascular pattern observed during the dissection of cadavers intended for teaching purposes.

A descriptive and observational study of renal vascular anatomy was carried out by dissecting 16 renal blocks from 8 cadavers donated to science and used for teaching at the Faculty of Medicine of the University of Zaragoza.

The prevalence of arterial variations was 75% (56.3% for polar renal arteries, 12.5% for pre-hilar branching and 6.25% for double communicating arterial arch) and venous was 62.5% (12.5% for polar renal veins, 25% for late venous confluence, 6.25% for triple renal vein and 18.75% for double circumaortic renal vein).
We conclude that the renal vascular anomalies occur with high frequency; for this reason, knowledge of these anomalies is extremely important for the correct planning of numerous medical-surgical activities.

Key words: renal artery, renal vein, vascular variation, anatomical variants, polar artery, circumaortic renal vein, renal vascular arch, renal surgery

INTRODUCTION

In classical anatomical terminology, the renal vasculature is generally described by a renal artery and a renal vein, a branch originating from the abdominal aorta and tributary to the inferior vena cava, respectively. The arterial supply of the kidney arises bilaterally and anteriorly from the abdominal aorta at the level of the lumbar vertebrae L1 and L2, approximately one centimetre below the exit of the superior mesenteric artery and, at a variable distance from the renal hilum, divides into its two terminal branches, the anterior or prepyelic artery (AP) and the posterior or retropyelic artery (RP), which in turn divide into segmental branches. In addition, collateral branches are distributed from this renal artery that will give rise to the inferior suprarenal arteries and branches for the renal capsule and proximal part of the ureter [20,31]. On the other hand, the venous return is responsible for draining blood from venous branches homonymous with the arteries of both kidneys into the inferior vena cava where it empties approximately at the level of the second lumbar vertebra. Generally, they are located in an anterior position with respect to the artery and follow a reverse trajectory to the latter [16].

However, this described vascular pattern presents numerous anatomical variations in terms of their number, origin and course. It is considered that variations in the renal arteries, in general, are found in about 35% of cases, while alterations in the renal veins, which are less frequent, occur in 18% of the observed cases [7,9].

Knowledge of the normality and variations in the vascular system of the kidney is extremely important for proper medical-surgical care, especially when planning various interventions (renal transplantation, angiography and/or aneurysm repair, among
Anatomical variations of the renal vessels are considered one of the most prevalent vascular anomalies, both arterial and venous, occurring in approximately 35% and 18% of individuals respectively [7,9]. Incidence varies according to ethnicity, ranging from 4% to 61.5% [11,12] in the renal arterial system and between 8 and 38.8% in the venous system [6]; the number of accessory arteries, between 3% and 30% unilaterally and 10% bilaterally [1,4, 27, 29, 36], and accessory veins, more frequent in the right renal vein (16.6%) compared to the left (2.1%) [15]; and the method of study, computed tomography or dissection [12]).

Embryological development plays a major role in its prevalence, with an association between the presence of accessory renal vessels and evidence of arrested uniform development of the kidney [37] Organs that migrate extensively during development, such as the kidneys, may retain vessels from their initial location or incorporate new vessels from the invaded region. Initially, the permanent primordial kidneys are located in the pelvis in close proximity to each other and, as the embryo grows, they gradually separate and relocate in the abdomen, reaching their usual position by the ninth week of gestation. During the early stage, the renal arteries originate from the common iliac arteries and as the kidneys ascend they receive new branches from the distal aorta. When the kidneys are located in their adult position they receive most of their arterial branches from the abdominal aorta. Thus, as a rule, the caudal branches from the initial renal vessels involute and disappear, while the cranial branches from the abdominal aorta become the permanent renal arteries [21]. This could explain the cases of accessory renal vessels arising from iliac, sacral or inferior mesenteric arteries, as they could be considered as persistence of primitive renal arteries.

The main objective of this study was to carry out a descriptive study of the vascular patterns observed in the dissection of 16 renal blocks belonging to cadavers destined to teaching for the Degree of Medicine.
MATERIALS AND METHODS

A descriptive and observational study of renal vascular anatomy was carried out by dissecting renal blocks belonging to the bodies donated to science, and used for teaching the Degree of Medicine, from the Department of Human Anatomy and Histology of the Faculty of Medicine in the University of Zaragoza.

The study in cadavers was carried out by dissecting a total of eight cadavers, previously destined for use in teaching, aged between 70 and 99 years, of which 5 were male (62.5%) and 3 females (37.5%), obtaining a total of 16 renal blocks (8 left and 8 right kidneys).

During the dissection protocol, both renal structures were studied as a block, to subsequently study them individually and assess the presence of arterial variations for comparison with those described in the literature.

RESULTS

Dissection showed the presence of different anatomical variations related to the vascular supply of the kidney, while renal anatomy showed no alterations in size, position and structure in any of the cases studied.

The main variations observed are classified in Table 1, their prevalence in Table 2 and some of them are shown in Figures 1 and 2.

In addition, the following table shows the percentage values of the vascular anatomical variations found in relation to the number of dissected renal structures (Table 2).

DISCUSSION

The presence of variations in the renal vascular system is considered of utmost importance, being essential for radiologists, surgeons and urologists to have a global anatomical vision that allows them to establish a good approach and surgical plan for different pathologies of the renal-ureteral system.
In this study we have observed the presence of anatomical polymorphisms of the vascularisation of the kidney in a total of 16 renal structures (8 left and 8 right). Of the total number of renal blocks dissected in the study, we identified 75% and 62.5% of variations at the arterial and venous levels, respectively. These results reflect a higher frequency than previous studies, such as Cruzat et al. (2013) [7] who consider a prevalence of 35% of arterial variations, Gebremickael et al. (2021) [10] who describe their presence in 38.5% of the Ethiopian population and Budhiraja et al. (2013) [3] with an incidence of 59.5% of variations with respect to normality in the Indian population. On the other hand, the venous anomalies observed in our study (62.5%) are higher than those described in the investigations by Ferreira et al. (2014) [9] and Mendez et al. (2016) [20] (18% and 31.9% respectively).

The pattern of arterial variations was more common on the right side (64.3%) than on the left (35.7%), while venous anomalies were equally distributed on both sides. These data are similar to those shown by Özkan et al. (2006) [25] and Ugurel et al. (2010) [35] in two renal helical CT angiographic investigations in a total of 855 and 100 patients respectively.

The vascular anatomical variations in the kidney with the highest incidence are the polar renal arteries. In fact, in the present study, this tendency is observed in 56.3% of the renal structures (in 9 of the 16 dissected kidneys), a higher percentage than that obtained by Satyapal et al. (2001) [30] of 27.7%, a result that is within the average mean prevalence of polar renal artery (RA) described by other authors such as Khamanarong et al. (2004) [17] and Çınar & Türkvatan (2016) [5] (17% vs. 31.3%).

Furthermore, supernumerary RAs can be divided according to their point of entry into the kidney, into superior and inferior polar arteries. In this regard, our study found a higher incidence of superior polar arteries compared to inferior ones (72% vs. 28%); data that differ from those obtained by Gebremickael et al. (2021) [10], who found a lower prevalence regardless of whether their entry point was inferior or superior and, in turn, highlighted a somewhat lower frequency of superior polar RAs compared to inferior ones (9.2% vs. 11.7%). Similarly, these supernumerary arteries may originate from the aorta or the main RA. Talovic et al. (2007) [34] described a higher prevalence
of aortic versus renal origin, a result similar to that obtained in this study (82% Ao vs 18% RA).

At the venous level, it is necessary to differentiate renal variations according to whether they occur on the right or left side. Several studies [5,18,26] have shown that multiple renal veins (RV) are more common on the right side, especially polar RV with a percentage of 24% described by Raman et al. (2007) [26], a result similar to that obtained in our study of 25%. In contrast, on the left side, the presence of multiple veins is not frequent, but a double circumaortic renal vein is found, also called "renal collar" by authors such as Sousa-Rodrigues et al. (2013) [32] and Haladaj et al. (2019) [13]. Beckmann et al. (1979) [2] described an incidence of 11% of renal collars compared to the 37.5% found in our study. Recognition of the retroaortic RV is essential, as this vessel may be mistaken during dissection of the interaortic and para-aortic canal as a lumbar vein or a variant of the gonadal vein and may be injured; moreover, it has been associated with the development of secondary renal venous hypertension due to the difficulty of drainage [28].

In our study, the rate of early branching of the main RA is 12.5% (6.25% on each side). This prevalence is within the range described in articles such as Özkan et al. (2006) [25], Holden et al. (2005) [14] and Raman et al. (2007) [26] on pre-hilar renal arterial branching, with a frequency of between 8.12 and 21% respectively. This variability may be due to the distance from which early branching was considered, as in some cases a division within 1.5 cm from the RA exit was considered early branching [5], while in other cases 2 cm was considered early branching [26] or even certain studies did not specify the exact distance [14,25].

Similarly, at the venous vascular level, late confluence of venous branches has also been observed in 25% of renal anatomical structures, 18.75% on the right side and 6.25% on the left. However, after review of numerous studies on variations in renal vascular anatomy, late RV confluence was identified in only a small number of cases, including Raman et al. (2007) [26], who described a prevalence of such variation of 10% on the right side and 17% on the left, and Çınar & Türkvatan (2016) [5], with a frequency of 4.1% and 3.2% respectively.
CONCLUSIONS

A large number of variations of the renal vasculature have been observed, therefore knowledge of the renal vasculature and its possible variations is extremely important during the planning of medical-surgical activities, especially uro-radiological ones, such as angiographic interventions, transplantations, renovascular reconstructions or partial renal resections.

Acknowledgements

The authors sincerely thank those who donated their bodies to science so that anatomical research could be performed. Results from such research can potentially increase mankind's overall knowledge that can then improve patient care. Therefore, these donors and their families deserve our highest gratitude.
