Disclaimer: The position statement represents the views of the authors and were produced after careful consideration of the scientific and medical knowledge and the evidence available at the time of their drafting. The authors and societies are not responsible in the event of any contradiction, discrepancy, and/or ambiguity between the position statement and any other official recommendations or guidelines issued by the relevant public health authorities, in particular in relation to good use of healthcare or therapeutic strategies. Health professionals are encouraged to take the position statement fully into account when exercising their clinical judgment as well as in the determination and the implementation of preventive, diagnostic, or therapeutic medical strategies.
ABBREVIATIONS

- ABPM — ambulatory blood pressure monitoring
- ACE-I — angiotensin-converting enzyme inhibitor
- AF — atrial fibrillation
- AFI — amniotic fluid index
- AGA — appropriate for gestational age
- AHI — apnea hypopnea index
- AKI — acute kidney injury
- ALT — alanine transaminase
- ARB — angiotensin receptor blocker
- ARR — aldosterone-to-renin ratio
- AST — aspartate aminotransferase
- AT — atrial tachycardia
- BAV — bicuspid aortic valve
- BMI — body mass index
- BNP — B-natriuretic peptide
- BP — blood pressure
- Bpm — beats per minute
- BPP — biophysical profile
- CABG — coronary artery bypass graft
- CAD — coronary artery disease
- CKD — chronic kidney disease
- CNS — central nervous system
- CoA — coarctation of the aorta
- CPAP — continuous positive airway pressure
- CPR — cerebroplacental ratio
- CTG — cardiotocography
- CV — cardiovascular
- DBP — diastolic blood pressure
- DIC — disseminated intravascular coagulation
- DM — diabetes mellitus
- ECMO — extracorporeal membrane oxygenation
- ECG — electrocardiography
- EF — ejection fraction
- ESC — European Society of Cardiology
- ESH — European Society of Hypertension
- EVA — early vascular ageing
- FDA — Food and Drug Administration
- FHR — foetal heart rate
- FIGO — International Federation of Gynaecology and Obstetrics
- FMD — fibromuscular dysplasia
- FNF — Fetal Medicine Foundation
- FPS — frame per second
- GFR — glomerular filtration rate
- HELLP — hemolysis, elevated liver enzymes, low platelet count
- HT — hypertension
- INR — international normalized ratio
- i.v. — intravenous
- IABP — intra-aortic balloon pump
- ICD — implantable cardioverter-defibrillator
- IUFD — intrauterine fetal death
- IUGR — intra-uterine growth restriction
- IVF — in vitro fertilisation
- LBBB — left bundle branch block
- LBW — low birth weight
- LDH — lactate dehydrogenase
- LQTS — long QT syndrome
- LVAD — left ventricular assist device
- LV EF — left ventricular ejection fraction
- MAP — mean arterial pressure
- MCA — middle cerebral artery
- MDS — multidisciplinary team
- MRA — mineralocorticoids receptor antagonist
- MRA s — mineralocorticoids receptor antagonists
- MRI — magnetic resonance imaging
- NT-STEI — non-ST elevation myocardial infarction
- NT-BNP — N-terminal pro-BNP
- NTS — non-stress test
- OGTT — oral glucose tolerance test
- OSA — obstructive sleep apnoea
- p.o. — per os
- PA — primary aldosteronism
- PAPP-A — pregnancy associated placental protein
- PCI — percutaneous coronary intervention
- PE — pre-eclampsia
- PI — pulsatility index
- PGF — placental growth factor
- PPCM — peripartum cardiomyopathy
- PP-GT — pheochromocytoma and paraganglioma
- PREVEND — Prevention of Renal and Vascular End-Stage Disease
- P-SCAD — pregnancy associated with spontaneous coronary artery dissection
- PTNT — Polish Society of Hypertension
- RAAS — renin-angiotensin-aldosterone system
- SBP — systolic blood pressure
- SCAD — spontaneous coronary artery dissection
- SDB — sleep-disordered breathing

- WPW — Wolff-Parkinson-White syndrome
1. INTRODUCTION

This document is the first joint expert opinion of three medical societies on hypertension in pregnancy. It aims at presenting the management of hypertension in pregnancy, with particular emphasis on pathophysiological differences, clinical manifestation and sequelae of pregnancy-induced hypertension and pre-eclampsia. The document is based on the analysis of existing guidelines, the regulation of the Minister of Health and a critical analysis of available data. The Regulation of the Minister of Health, which we repeatedly refer to in this expert position statement, albeit expired on 1 January 2019, still applies to this document and its detailed recommendations, due to its undoubted substantive value and the fact that it systematizes the management of normal and complicated pregnancy [1–9].

Elevated blood pressure (BP) in pregnancy poses a significant clinical challenge, and the observed trend towards delayed childbearing and later age of pregnant women contribute to its higher prevalence. Hypertension (HT) in pregnancy affects 6–10% of pregnancies in the United States and Europe. Women with chronic HT (1–5% of the general population) have a higher risk of pre-eclampsia (PE) than women without pre-existing HT (17–25% vs. 3–5%, respectively). Furthermore, 7–20% of women with chronic HT have poor BP control in pregnancy (excluding those with PE). Significantly elevated BP in pregnancy is a direct threat to maternal and foetal health and life. According to the WHO, HT and its complications are among the leading causes of mortality in pregnancy in developed countries (approx. 16%) [9–11].

Hypertension promotes low birth weight (LBW), increases the risk of PE superimposed on chronic HT and preterm birth, may cause placental abruption, leads to complications which require prolonged intensive care of a neonate with specialist neonatal treatment, and may cause intrauterine foetal death [12, 13].

PE is the most dangerous maternal complication of HT. PE is associated with a particularly high risk of complications harmful to the mother and foetus. Each year, PE causes over 500 thousand foetal and neonatal deaths and over 70 thousand maternal deaths worldwide [1, 12, 13].

Developing recommendations on the management of HT in pregnancy is challenging for two reasons — first, the number of studies, especially with prospective and randomized design, is limited, and second, approved indications and registry data limit the possibility to develop recommendations regarding drug classes. It is only possible to comment on the potential use of selected drugs [1, 2, 4, 9, 11].

Most guidelines and recommendations published to date have been developed separately by societies of cardiology/hypertension or by societies of obstetrics and gynaecology [1–9]. Therefore, a joint position statement was developed in order to avoid discrepant recommendations and to create a single practical document which could provide guidance for physicians responsible for the management of HT from pre-conception to the postpartum period.

2. ASSESSING THE STRENGTH OF RECOMMENDATION

The members of the working group who drafted this position statement have thoroughly reviewed the published results of studies of HT in pregnancy discussing its prevention, diagnostic and therapeutic management as well as long-term prognosis. The level of evidence and the strength of recommendations for each option are balanced and categorised using the previously defined grading systems shown in Tables 2.1 and 2.2 in harmony with the recommendations of the European Society of Cardiology. In order to simplify the message when presenting individual recommendations, the class of recommendation was omitted, and the following phrases were used instead as equivalent to the classes of recommendations:

- recommended/indicated (class of recommendation I);
- should be considered (class of recommendation IIa);
- may be considered (class of recommendation IIb);
- not recommended (class of recommendation III).

Furthermore, the recommendations listed in the tables were colour-coded: green (class of recommendation I), yel-

<td>Is not recommended</td>
</tr>
</tbody>
</table>
low (class of recommendation Ila and IIb) and red (class of recommendation III) [3]. Finally, the quality of research-derived evidence constituting a basis for recommendations was assessed and expressed as levels (Tab. 2.2).

3. DEFINITIONS AND THE CLASSIFICATION OF HT IN PREGNANCY

Based on the differences in pathophysiology, clinical manifestation and management, HT during pregnancy can be divided into two distinct conditions (Fig. 3.1) [1, 4]:

- **chronic HT** — preexisting or with the onset before 20 gestational weeks, and typically persisting up to 6 weeks postpartum, which can be classified into:
  - primary (essential) HT,
  - secondary HT;

- **hypertensive disorders of pregnancy** — with the onset after 20 gestational weeks, which can be classified into:
  - pregnancy-induced HT with the onset after 20 gestational weeks, which resolves within 6 weeks postpartum,
  - pre-eclampsia.

It should be noted that the two conditions are not mutually exclusive, that is, a woman with chronic HT may develop PE — PE superimposed on chronic (pre-existent) HT.

A number of other possible clinical scenarios in pregnancy have been presented in Table 3.1.

It is emphasized that the cut-off point of 20 gestational weeks should only be considered a rough approximation and clinical evaluation should primarily inform the decision-making. Differentiation between different hypertensive disorders of pregnancy is further hindered by the fact that the maximum physiological blood pressure drop occurs at 16–18 gestational weeks, which may mask chronic HT, and the BP only returns to pre-conception values in the third trimester. Additionally, pre-conceptive BP values are often unknown [14]. Regardless of the above, physiological pregnancy is associated with a blood pressure drop. This response is also preserved in women with chronic HT. Pregnancy-induced HT superimposed on chronic HT should therefore always be considered with a sudden onset of high blood pressure in pregnancy.

4. MANAGEMENT OF HT IN WOMEN AT REPRODUCTIVE AGE

Diagnostic management and treatment of HT in women planning to conceive may affect the course of pregnancy as well as maternal and foetal outcomes [15]. Due to significant unintended pregnancy rates, any woman having menstrual cycles presenting with HT should be considered potentially pregnant. Therefore, this document outlines both the general principles of chronic HT management in women at reproductive age and the specific recommendations of HT management in women planning to conceive.

4.1. Treatment of HT in women at reproductive age

The current guidelines for the management of HT do not provide for a separate diagnostic algorithm applicable to women at reproductive age, including those planning to conceive [2, 4].

In women with elevated office BP readings, it is recommended to exclude white coat HT and confirm the HT diagnosis with BP readings obtained elsewhere — using either 24-hour ambulatory blood pressure monitoring or home blood pressure (Fig. 4.1). If out-of-office BP readings cannot be obtained, it is recommended to confirm the HT diagnosis using repeated office measurements, preferably taken by a nurse [16, 17].

The guidelines for the management of HT point to the urine albumin test as a preferred severity assessment of HT-induced target organ damage. However, this test is not commonly used in Poland [3, 4]. On the other hand, the guidelines for the management of HT in pregnancy indicate the validity of urine protein test rather than urine albumin test, whilst not stating a preferred method (especially quantitative assay) (Tab. 4.1) [1, 8]. Considering the need to develop practical guidelines which ensure standardised management, we recommend that every woman at...

Figure 4.1. Management of hypertension (HT) in women at reproductive age

- Confirm the diagnosis of HT
- Assess BP control in out-of-office BP measurements
- Implement lifestyle modifications
- Calcium channel blockers, β-blockers or their combination should be considered
- Thiazide/thiazide-like diuretics diuretics may be considered
- Conversion to drugs approved for use in pregnancy may be considered at the pregnancy/IVF planning stage
- Do not use/discontinue:
  - angiotensin-converting enzyme inhibitors
  - angiotensin receptor blockers
  - mineralocorticoid receptor antagonists

www.journals.viamedica.pl/ginekologia_polska

Aleksander Prejbisz et al., Management of hypertension in pregnancy
reproductive age presenting with HT be screened for proteinuria at least once using a qualitative assay (urinalysis or strip test). If proteinuria is detected, a quantitative assay should follow. On a similar note, a quantitative urine protein assay should be considered in each woman planning to conceive who presents with HT (Fig. 4.2). The preferred quantitative method has not been clearly determined. In an outpatient setting, the protein:creatinine ratio in the morning urine sample or 24-hour urine collection may be considered (Tab. 4.1).

It is recommended to perform basic tests including, as per guidelines, full blood count, fasting glucose, lipid profile, sodium, potassium, uric acid and creatinine (with eGFR), liver function tests (AST, ALT), TSH, urinalysis with urine sediment examination and electrocardiography in each woman planning to conceive who presents with HT [3, 4].

Screening for secondary HT should be considered in each woman planning to conceive who presents with HT based on routine assessment findings and detailed medical history [3, 4, 18] (Tab. 4.2).

Due to their younger age, women planning to conceive may develop HT secondary to chronic kidney disease (e.g. vesicoureteral reflux, glomerulonephritis), renal artery stenosis from fibromuscular dysplasia, pheochromocytoma, coartation of the aorta or primary aldosteronism. Secondary HT affects about 0.2% of all pregnancies and is diagnosed in 2–5% of all pregnant women with HT treated in highly specialist centres [18]. Diagnostic management of HT in women planning to conceive should be further extended to include kidney ultrasound and renal artery Doppler ultrasound. Echocardiography should be considered in order to assess for complications and identify secondary causes of HT, such as coartation of the aorta in women with a detectable heart murmur on auscultation. The descending aorta should be assessed from the suprasternal notch window as an integral part of echocardiography [3, 4].

Women with chronic HT planning to conceive should undergo risk assessment for PE — this issue is discussed in detail in Chapter 5.6.1.

4.2. Treatment of HT in women at reproductive age

Women at reproductive age should be encouraged to implement lifestyle modifications as per current guidelines on the management of HT, with particular emphasis on those aspects which are likely to affect foetal wellbeing, that is, smoking cessation, alcohol abstinence and weight loss [4].

**DIAGNOSIS OF HYPERTENSION IN WOMEN AT REPRODUCTIVE AGE — RECOMMENDATIONS**

- It is recommended to confirm the diagnosis of HT in women at reproductive age with out-of-office BP reading Level B
- Qualitative screening for proteinuria is recommended in each woman at reproductive age with HT Level C
- A quantitative determination of urinary protein should be considered in each woman with HT planning to conceive Level C
- Basic tests including full blood count, fasting glucose, lipid profile, sodium, potassium, uric acid and creatinine (with eGFR), TSH, liver function tests (AST, ALT), urinalysis with urine sediment examination and ECG are recommended in each woman with HT planning to conceive Level C
- Screening for secondary HT is recommended in women at reproductive age with HT in whom abnormal history, physical examination or laboratory test findings indicate a secondary cause of HT Level C
- Kidney ultrasound and renal artery Doppler ultrasound are recommended in women with HT planning to conceive in order to exclude chronic kidney disease and renal artery stenosis from fibromuscular dysplasia Level C
- Echocardiography should be considered in women with HT planning to conceive, as a part of diagnostic evaluation Level C
Clinical decision-making regarding pharmacotherapy of HT in women at reproductive age should be based on the same principles as in other patients considering individual risk profile, haemodynamic and metabolic profile, with a preference for compound products to be used as a first-line treatment [3, 4]. However, reproductive plans and limited use of potentially teratogenic drugs in women at reproductive age always need to be considered, as well. Due to high unintended pregnancy rates, renin inhibitors, angiotensin-converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARB) and mineralocorticoid receptor antagonists (MRA) are not recommended in women at reproductive age and should only be used in patients with special indications (type 1 diabetes mellitus, diabetic kidney disease, heart failure, chronic kidney disease, primary aldosteronism). If these drug classes are used, patients should be informed about their potential teratogenic potential and the need to immediately discontinue treatment in the event of pregnancy (such information should also be provided to all women at reproductive age) [2–4]. Clonidine and calcium channel blockers (CCB) should be preferred for the management of hypertensive emergency in women at reproductive age.

Out of the 5 basic classes of hypotensive drugs, calcium channel blockers (preferably dihydropyridine derivatives) and/or b-blockers should be considered in women at reproductive age. Thiazide/thiazide-like diuretics may also be considered. However, these have to be discontinued in pregnancy (Fig. 4.1). Thiazide/thiazide-like diuretics may be considered in women at reproductive age planning to conceive (Chapter 7.2). Conversion to hypotensive drugs recommended in pregnancy can be considered in women planning to use assisted reproductive technology. Once pregnancy has been confirmed in a woman with chronic HT, a conversion to treatment with the well-established favourable safety profile in pregnancy is the best course of action (Chapter 5.7).

Conversion to hypotensive drugs typically used in pregnancy (especially labetalol and extended-release nifedipine, should they be approved in Poland in the future) can be considered in women at reproductive age planning to conceive (Fig. 4.1). Conversion to hypotensive drugs recommended in pregnancy can be considered in women planning to use assisted reproductive technology. Once pregnancy has been confirmed in a woman with chronic HT, a conversion to treatment with the well-established favourable safety profile in pregnancy is the best course of action (Chapter 5.7).

5. MANAGEMENT OF HIGH BLOOD PRESSURE IN PREGNANT WOMEN

5.1. Diagnosis of hypertension and blood pressure measurements

5.1.1. Blood pressure measurements in pregnancy

The office BP readings taken using a validated, automatic blood pressure monitor should be preferred [4]. Recommendations on the techniques of office BP measurement in pregnant women are shown in Table 5.1.

Although some documents mention 24-hour BP monitoring as the preferred out-of-office measurement technique, we believe that commonly available home BP measurement is a sufficient alternative to out-of-office measurement. The principles of home BP measurement are shown in Table 5.1.

The correct cuff size is crucial for both office and out-of-office BP measurements. For the mid-upper arm circumference above 33 cm, a large cuff should be used [3, 19]. A list of validated automatic blood pressure monitors, for both office and out-of-office BP measurements, can be found at http://bhsoc.org/bp-monitors/bp-monitors/ [20].

24-hour BP monitoring should be considered in the following clinical scenarios:

— to rule out white coat hypertension;
— to rule out masked HT in patients with high-normal BP (130–139 / 85–89 mm Hg) and metabolic disorder;
— to monitor treatment efficacy alongside home BP measurements (if available);

Conversion to hypotensive drugs typically used in pregnancy (especially labetalol and extended-release nifedipine, should they be approved in Poland in the future) can be considered in women at reproductive age planning to conceive (Fig. 4.1). Conversion to hypotensive drugs recommended in pregnancy can be considered in women planning to use assisted reproductive technology. Once pregnancy has been confirmed in a woman with chronic HT, a conversion to treatment with the well-established favourable safety profile in pregnancy is the best course of action (Chapter 5.7).
Diagnosis of HT in pregnancy

The diagnosis of HT in pregnancy is based on office BP readings. A diagnosis of HT should be made when systolic BP is ≥ 140 mm Hg and/or diastolic BP is ≥ 90 mm Hg. HT in pregnancy is defined as mild (BP of 140–159/90–109 mm Hg) or severe (BP ≥ 160/110 mm Hg). The diagnosis of mild HT should be confirmed in out-of-office BP readings. A diagnosis of HT should be made when systolic BP ≥ 140 mm Hg and/or diastolic BP ≥ 90 mm Hg.

The first measurement should be taken on both arms, the subsequent measurements should be taken on the arm with a higher BP. The BP should be determined based on 2 consecutive readings taken on the same occasion at 1–2-minute interval. The third reading should be taken (and included in calculating the mean BP) if there is an inter-measurement difference above 10 mm Hg.

Office measurement

- Cuff size suitable for the patient’s arm circumference (ideally, the cuff length should encircle 80% of arm circumference, and cuff width should be equal to 40% of arm circumference)
- The patient must avoid caffeine intake and smoking for at least 30 minutes prior to measurement
- A few-minute rest is recommended prior to each measurement, with the patient sitting up supported in a quiet room
- The patient should sit up supported, with no tight clothing on the arm, her arm supported with the elbow at the level of the fourth intercostal space
- The cuff should be at heart level, regardless of the patient’s body position
- The measurements should be taken using the technique for the office BP measurements

Home measurement

- The measurements should be taken on 7 consecutive days preceding the medical appointment to determine BP control in women with chronic HT during the 1st trimester and to determine BP values in women with white coat HT or transient HT
- The measurements should be taken every day in women with chronic HT during the 2nd and 3rd trimester, and in women with pregnancy-induced HT and PE
- The measurements should be taken in the morning and in the evening at regular intervals (e.g. 06.00 and 18.00, 07.00 and 19.00 etc.). On each occasion, 2 consecutive readings should be taken at several-minute intervals (2 × 2 scheme)
- The measurements should be taken directly before taking medications, and in the morning measurement before the first meal of the day
- The measurements should be taken using the technique for the office BP measurements
- The patient should record the BP values in the 7-day Home Blood Pressure Monitoring Chart (Appendix 1). It is possible to use blood pressure monitors with built-in memory or a printer
- For the purposes of calculating the mean home BP, the readings obtained on the first day are disregarded

If there is a significant discrepancy between the office and home BP readings and/or high BP variability; in patients with diabetes mellitus or CKD.

5.1.3. Assessing the dynamics of BP changes in pregnancy

There is no optimum algorithm for home BP monitoring in pregnant women. When developing the algorithm presented in this document, we were primarily guided by the need to monitor BP more closely in the second and third trimester alongside the need to take two consecutive measurements on each occasion in order to provide reliable readings [21]. In order to assess BP control in pregnant women treated for HT in the first trimester or in order determine BP in pregnant women with white coat HT, home measurements are recommended with a 7-day algorithm (Appendix 1) to be followed in a week preceding each monthly appointment and 2–3 readings per week outside the 7-day periods. Home BP measurements, involving 2 consecutive readings at 1–2-minute interval in the morning and 2 consecutive readings at 1–2-minute interval in the evening, both before meals and taking medications (the 2 × 2 scheme), are recommended in women with chronic HT in the second and third trimesters and in women with pregnancy-induced HT or PE.
Figure 5.1. Diagnosis of hypertension (HT) and blood pressure (BP) measurements in pregnancy. *Mean of home BP monitoring or mean of daily ABPM; **Depending on the clinical presentation and next appointment availability.

- **1st appointment**
  - The mean of two in-office BP readings taken 1–2 minutes apart
  - SBP < 140 mm Hg and DBP < 90 mm Hg
  - SBP 140–159 mm Hg and/or DBP 90–109 mm Hg
  - SBP ≥ 160 mm Hg or DBP ≥ 110 mm Hg
    - Repeate the reading within 15–30 minutes

- **1st trimester**
  - after 7 days
  - within a few days**
  - Home blood pressure measurement or ABPM

- **2nd appointment**
  - 1st trimester
    - after 7 days
    - within a few days**
  - Home blood pressure measurement or ABPM
    - SBP < 135 mm Hg and/or DBP < 85* mm Hg
    - SBP ≥ 135 mm Hg and/or DBP ≥ 85* mm Hg
    - If out-of-office BP measurement is not available — in-office BP should be taken at the next appointment

- **Further management**
  - Normal BP
    - In-office measurement once a month. Consider home blood pressure monitoring or ABPM if indicated
  - White coat HT
    - Home blood pressure monitoring (7 days) prior to each antenatal appointment + 2/3 times a week in other weeks, consider periodic ABPM
  - Transient pregnancy-induced HT
    - 1st trimester — home blood pressure monitoring (2 × 2 scheme) for 7 days prior to each antenatal appointment, 2nd and 3rd trimester — home blood pressure monitoring every day (2 × 2 scheme); consider periodic ABPM
    - Daily home BP monitoring (2 × 2 scheme), periodic ABPM should be considered

*SBP ≥ 160 mm Hg or DBP ≥ 110 mm Hg
**Severe HT

  - Daily home BP monitoring (2 × 2 scheme), periodic ABPM should be considered

Figure 5.1. Diagnosis of hypertension (HT) and blood pressure (BP) measurements in pregnancy. *Mean of home BP monitoring or mean of daily ABPM; **Depending on the clinical presentation and next appointment availability.
BP readings obtained in 24-hour BP monitoring better predict the PE and IUGR than office BP readings. However, 24-hour BP monitoring does not offer sufficient sensitivity and specificity to be recommended as a method to assess the risk of these conditions [22].

5.2. Diagnostic test in pregnant women with HT

Women with chronic HT should be provided multidisciplinary care involving a consultant obstetrician/gynaecologist and a consultant cardiologist/clinical hypertension specialist. As HT in pregnancy may be secondary to CKD, each pregnant woman with CKD should also be assessed by the nephrologist. Further management and the frequency of follow-up appointments will be determined by the nephrologist depending on the clinical presentation of the pregnant woman, the presence of proteinuria and routine laboratory test findings (including eGFR). Following a confirmation of pregnancy by the consultant gynaecologist, it is recommended to perform basic tests including liver enzyme tests (AST, ALT, LDH), liver function tests (INR, bilirubin and albumin levels), serum creatinine, sodium, potassium and quantitative urine protein test at the first appointment with a consultant cardiologist/clinical hypertension specialist [1]. The results of these tests enable assessing complications of chronic HT and facilitate the diagnosis of PE after 20 gestational weeks.

Pregnant women with HT should be assessed for secondary HT based on medical history, physical examination and laboratory test findings. Table 4.2 shows the symptoms and test findings which may be suggestive of secondary HT as well as screening for secondary HT, which may be used in pregnant women.

As part of routine antenatal care, each pregnant woman is regularly screened for proteinuria during scheduled follow-up appointments.

The qualitative screening for proteinuria includes:
- urinalysis, or alternatively
- strip test — automated dipstick tests may be used with (+) considered a finding indicative of the need for further investigations and (++) corresponding to proteinuria of 1 g/L [23].

Some guidelines recommend quantitative screening for proteinuria by strip test. However, this method is hardly used in Poland. A reliable assessment for proteinuria should be based on 24-hour urine collection or protein/creatinine ratio determination in the urine sample (Tab. 4.1) [6, 8, 24, 25]. With any abnormal kidney function tests findings (serum creatinine and electrolytes, urinalysis), kidney ultrasound is recommended [1].

The algorithm for diagnostic investigations in pregnant women with chronic HT is summarized in Table 5.2. In the event of known PE without proteinuria as well as upon any change to clinical presentation, regular monitoring of uri-
nary protein excretion, serum haemoglobin level, platelet count, liver enzyme (AST, ALT) levels, and serum creatinine level is indicated [1, 26].

5.3. Echocardiography in pregnant women with hypertension

Being the most commonly performed diagnostic imaging investigation of cardiovascular diseases, the transthoracic echocardiography (TTE) enables the assessment of cardiac morphology and function [27]. TTE is also a preferred diagnostic imaging method in pregnant women as it is harmless, widely available, relatively inexpensive and highly repeatable. Due to the growing number of pregnant women with cardiovascular diseases and the delayed childbearing tendency currently seen in Poland, it can be expected that TTE will be used increasingly more often in this group of patients [2]. Pregnancy is associated with physiological adaptation of the cardiovascular system altered haemodynamic

*As per the Minister of Health regulation; ** more frequent appointments should be considered in women with a higher risk of complications (see Chapter 5.6.2.), the frequency of appointments and diagnostic tests should be determined based on clinical presentation, and in particular, changes to clinical presentation, and in particular, changes to clinical presentation.
The MRI imaging using high-field devices, above 3T, is not prolonged in the first trimester, unless clinically appropriate. However, the duration of colour (MRI) do not use ionizing radiation and are therefore considered potentially harmful to the developing foetus. Nevertheless, it should be emphasized that Doppler imaging is considered safe as long as the embryo/foetus lies outside the Doppler ultrasound beam, which is of crucial importance for the evaluation of renal arterial flow.

The transthoracic echocardiography should be considered in pregnant women with HT in order to evaluate heart function and morphology, including the assessment for left ventricular hypertrophy and the presence of cardiovascular symptoms. The transthoracic echocardiography should be performed in pregnant women with the onset of new or unexplained cardiovascular symptoms.

Diagnostic imaging using ionizing radiation is usually considered potentially harmful to the developing foetus. Nevertheless, it should be emphasized that the risk for the foetus depends on the radiation dose and pregnancy stage at the time of the procedure. Foetal exposure to radiation dose below 50 mGy even in the first trimester is not considered harmful to the foetus. It should be noted that a computed tomography of abdomen or pelvis, if performed appropriately, is associated with radiation exposure below 35 mGy (typically 10–25 mGy) [36]. Even lower exposure should be expected if the foetus is not directly exposed to the radiation beam. For example, computed tomography of the pulmonary circulation is associated with foetal exposure to 0.01–0.1 mGy, whereas the ionizing radiation dose...
exceeding 100 mGy is considered harmful to the foetus [37]. Similarly, foetal exposure to radiation during mammography was found to be minimal and is, therefore, considered safe [38].

That is why the American College of Obstetricians and Gynecologists’ Committee on Obstetric Practice makes the following recommendations regarding diagnostic imaging procedures during pregnancy:

- Ultrasonography and magnetic resonance imaging (MRI) are not associated with the risk to the foetus and are the imaging techniques of choice for the pregnant patient. As a principle, though, they should be used prudently and only when use is expected to answer a relevant clinical question.
- Radiation exposure through radiography, computed tomography (CT) scan, or nuclear medicine imaging techniques is at a dose much lower than the exposure associated with foetal harm. If these techniques are necessary in addition to ultrasonography or MRI or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient.
- The use of gadolinium contrast with MRI should be limited. It may be used as a contrast agent only if it significantly improves diagnostic performance and is expected to improve foetal or maternal outcome [29].

5.5. Assessing foetal wellbeing

Foetal wellbeing assessment is an essential part of antenatal care in women with HT or PE. As a result of abnormal (i.e., high-resistance) uteroplacental circulation, the maternal body needs to generate increasingly higher blood pressure in order to meet the increasing foetal demand for oxygen and nutrients. Abnormal placentation significantly reduces spiral artery diameter. As a result, foetal oxygen intake gradually decreases, causing IUGR and posing a risk to foetal wellbeing. A chain of events triggered by chronic foetal hypoxia is shown in Figure 5.2. There are at least several established methods for foetal wellbeing assessment which may be used in pregnant women with HT or PE. The key ones have been listed below.

5.5.1. Foetal movement counting

Subjective foetal movement counting by a pregnant woman is based on evidence that foetal movements are suppressed in response to hypoxemia [39]. Despite a commonly held view that extensive diagnostic management and intensive foetal wellbeing monitoring are appropriate in patients reporting decreased foetal movements, there is no clear guidance as to the frequency or scope of such monitoring. However, daily foetal movement counting (even three times a day after the main meals) has been suggested (Fig. 5.3).

5.5.2. Cardiotocographic foetal monitoring

Cardiotocography (CTG) is an established method of intensive foetal wellbeing surveillance. A normal cardiotocogram indicating proper oxygen delivery to the foetal CNS is characterized by normocardiac baseline foetal heart rate (FHR 110–160 bpm), moderate baseline FHR variability (amplitude of 10–25 bpm), the presence of at least two accelerations and the absence of decelerations within a 30-minute window. However, subjective interpretation is a downside of cardiotocography. In order to ensure objective assessment, modern foetal monitors offer computerized analysis and calculation of short-term variation (STV, the beat-to-beat interval) [40]. In an immature foetus, the STV < 3 ms is considered abnormal.

5.5.3. Foetal growth and amniotic fluid volume monitoring

Ultrasonography is a crucial aspect of foetal wellbeing assessment. The aim is to assess foetal anatomy and growth, amniotic fluid volume as well as to confirm normal placental location. Placental insufficiency secondary to PE often leads to intrauterine growth restriction (IUGR), which is associated with a high risk of iatrogenic preterm birth and prematurity [41]. All foetal biometry parameters should fall in the range of 2 standard deviations from the normal mean for gestational age. The diagnosis of intrauterine growth restriction should prompt the clinician to assess the blood flow in the

---

*Figure 5.2. The effect of placental insufficiency on foetal circulation*
middle cerebral artery of the foetus and the umbilical arteries (as well as in the ductus venosus in selected cases). The uterine artery blood flow should be assessed to determine whether IUGR is secondary to decreased placental perfusion. Furthermore, algorithms based on uterine artery flow resistance index may be useful in selected clinical scenarios in order to determine the optimal gestational age for delivery.

5.5.4. A foetal biophysical profile

A biophysical profile (BPP) uses a combination of ultrasound and cardiotocography. The biophysical profile assumes that the real-time ultrasound foetal observation combined with assessment of selected parameters may offer better prognostic value than the CTG alone [42]. The assessment of foetal movements, foetal breathing movements and foetal tone combined with non-stress test and estimation of amniotic fluid volume has been suggested to reduce the false negative results observed with the non-stress test or foetal movements alone. The biophysical profile correlates well with the cord blood pH and accurately predicts foetal acidosis [43, 44]. The BPP is usually recommended once a week.

5.5.5. Foetal blood flow assessment

The maternal and foetal blood flow velocimetry provides information about the uteroplacental circulation and foetal response to potential hypoxia (Fig. 5.4). Placental vascular remodelling, as seen in PE, causes gradual hemodynamic changes in fetoplacental circulation. Doppler-assessed umbilical artery flow parameters become abnormal when 60 to 70 per cent of the tertiary villous vessels are damaged [45]. As a result of hypoxia, vascular resistance in the foetal middle cerebral artery decreases, but it increases in the foetal aorta in order to preferentially direct blood flow to the foetal brain and heart [46]. In extreme cases, the end-diastolic flow in the umbilical artery is absent (and later reversed), followed by increased venous resistance (ductus venosus, umbilical vein, inferior vena cava). Changes in Doppler-assessed foetal circulatory parameters correlate with foetal acidosis [47]. Doppler blood flow assessment should be performed in patients with HT or PE depending on indications.

5.6. Preconception planning and obstetric care in patients with pre-existent HT

The aim of obstetric care in women with HT is to reduce the risk of maternal and foetal complications, as well as to achieve the lowest possible neonatal morbidity and mortality. This can be achieved through appropriate assessment and preconception counselling, early antenatal care and frequent antenatal appointments, timely delivery and appropriate postpartum management.

5.6.1. Preconception care

Preconception planning in women with chronic HT and history of pregnancy-induced HT should be careful and include obstetric consultation as well as other specialist
consultations, if indicated. Preconception care should focus on obstetric history and history of chronic diseases (Tab. 5.4), as well as include necessary laboratory tests and diagnostic imaging.

Pregnancy is not recommended in women with inadequate HT control despite optimal use of three antihypertensive medications as well as in women with secondary HT without treatment addressing the underlying cause of HT (see Chapter 4.2 and Tab. 4.2). A patient with suspected secondary HT should be assessed by a consultant clinical hypertension specialist or nephrologist (depending on creatinine level and suspected chronic kidney disease) as a part of preconception care [6]. Medication review should be carried out as a part of preconception care — see Chapter 4.3. Birth defect prevention, primarily of the central nervous system, with 400–800 micrograms of folic acid continued for at least 3 months prior to conception should also be recommended [48]. Daily dose of folic acid in patients with pre-existent obesity should be about 800 µg [49].

5.6.2. Antenatal care

The most frequent gestational complications in women with HT include PE superimposed on chronic HT (up to 50% in patients with severe HT) and its complications: IUGR,
premature placental abruption, prematurity (including iatrogenic), foetal mortality (perinatal mortality is 3–4× higher than in the general population). Chronic HT in pregnancy is considered a significant risk factor of PE. However, there has been no evidence to date that good BP control reduces the incidence of PE superimposed on chronic HT. Excessive BP reduction may be detrimental to placental vasculature and foetal development [9]. At the same time, using hypo‑tensive drugs in a woman with chronic HT may potentially be harmful [10]. Other risk factors include HT duration of 5 or more years; age > 35 y.o.; HT duration of 5 or more years; HT treated with 2 or more medications; history of obstetric complications (PE, premature perinatal abruption); chronic diseases: left ventricular dysfunction, retinopathy, lipid disorders, microangiopathy, stroke, diabetes, chronic kidney disease, connective tissue diseases or the presence of lupus anticoagulant [13].

Pregnant women with these risk factors are more likely to develop rare life-threatening complications, including hypertensive encephalopathy, pulmonary oedema, retinopathy, intracerebral haemorrhage or acute kidney injury [53]. The risk of obstetric complications increases with age, HT duration, and in particular the severity of secondary target organ damage. Proteinuria in early pregnancy is an independent risk factor associated with higher rates of preterm birth, small for gestational age neonates and intraventricular haemorrhage [8]. Patients with chronic kidney disease, diabetic angiopathy, severe collagen vascular disease, cardiomyopathy or coarctation of the aorta should be informed about the adverse effect of these conditions on pregnancy at the preconception stage. Patients with severe, uncontrolled HT, severe impairment of renal function in early pregnancy and pre‑existent left ventricular heart failure have been identified as a particularly high-risk group.

The proposed obstetric care algorithm including diagnostic investigations is shown in Table 5.2. In women with well‑controlled BP, after ruling out other maternal and foetal complications, delivery is recommended after 38 gestational weeks. Hospital referral is recommended in patients with systolic BP ≥ 160 mm Hg or diastolic BP ≥ 110 mm Hg [1, 14]. Hospital referral should also be considered upon the onset of symptoms suggestive of PE (Tab. 6.2 and 6.3).

The incidence and sequelae of maternal and foetal complications in patients with HT with a higher risk of complications depend on the underlying cause of HT as well as the severity of target organ damage. Antenatal care in these patients should be provided by maternal foetal medicine consultant, with multidisciplinary input from consultant cardiologist/clinical hypertension specialist and other consultants, if indicated.

5.7. Treatment of hypertension in pregnant women

5.7.1. Non-pharmacological management of hypertension in pregnant women

Lifestyle modifications, including behavioural changes improving foetal and neonatal outcomes, such as smoking cessation and alcohol abstinence are recommended at the preconception stage, in pregnancy and postpartum [54]. Cigarette smoking is the most common addiction in Polish women at reproductive age and affects approximately 30% of pregnant women [55]. Cigarette smoking in pregnancy adversely affects foetal development, e.g. due to the effect of carbon monoxide contained in tobacco smoke, which binds to haemoglobin and reduces foetal oxygen supply [56].

The teratogenic effect of alcohol on the foetus was first described back in the 1960s. The recommendations of the International Federation of Gynaecology and Obstetrics (FIGO) and the Polish expert opinion statement are, therefore, unambiguous and recommend the active promotion of alcohol abstinence in women planning to conceive, pregnant or breastfeeding [54, 57].

Although no particular diet is recommended in pregnancy, a good diet is based on the general healthy nutrition principles for adults (for example, the Mediterranean diet). A balanced, varied and healthy diet is very important during pregnancy. According to FIGO, a diet should be high in vegetables, fruit, pulses and whole grains. Animal products (milk, dairy, lean meat), as well as oily saltwater fish, should be consumed in moderation (fish which may contain higher concentrations of mercury, e.g. shark, swordfish, king mackerel should not be consumed), whereas products high in carbohydrates and saturated fatty acids should only be consumed occasionally [54].

Optimum body weight should be achieved prior to conception. The energy requirement in pregnancy increases slightly (by about 10%) in comparison to the preconception period. According to FIGO, based on American guidelines, the recommended weight gain during pregnancy in women with normal pre-pregnancy BMI (18.5–25 kg/m²) is 11.5–16.0 kg. The recommended weight gain in overweight and obese women is 7–11.5 kg and 5–9 kg, respectively [54, 58].

A physically active adult with a body weight of about 70 kg needs about 2.5 litres of water per day (range from 1.5 to 3 litres, including about 700 ml of water contained in food). Pregnant and breastfeeding women should increase their daily water intake by about 300 ml and 600–800 ml, respectively. The daily recommended water intake in the second/third trimester and during breastfeeding is 3 litres and 3.8 litres, respectively. In the first trimester, the daily water requirement is the same as in a non-pregnant woman, i.e. 2.7 litres [59].

A significant reduction of table salt intake is not recommended in pregnancy. However, pregnant women should use iodised salt [54].

Daily intake of caffeinated beverages should be limited to not more than 200 mg of caffeine (one cup of coffee contains 50–160 mg of caffeine) in pregnant women [60, 61].

It is recommended to advise women with well-controlled BP who regularly exercised prior to conception to continue moderate physical activity [2, 4, 6, 54]. The research shows that moderate physical activity in pregnancy is not only safe but also improves maternal and foetal outcomes (e.g. it reduces preterm birth rates and the incidence of pregnancy-induced HT) [61–63].

Importantly, pregnancy should be used as an opportunity to educate patients on lifestyle modifications, including a healthy diet, which should continue even after childbirth [2].

5.7.2. Initiation of pharmacological treatment of hypertension in pregnancy and target blood pressure values

The guidelines published in recent years provide discrepant thresholds for treatment of HT. We recommend a BP threshold of ≥ 140 mm Hg systolic and/or ≥ 90 mm Hg diastolic for the treatment of chronic and pregnancy-induced HT in all pregnant women.

The ESC guidelines of 2018 [2] recommend higher BP threshold for the initiation of antihypertensive drug treatment in pregnant women with uncomplicated chronic HT (≥ 150/≥ 95 mm Hg), but there is no published evidence to support different treatment strategies in uncomplicated chronic HT (BP threshold ≥ 150/≥ 95 mm Hg) and gestational HT, pre-existing HT with the superimposition of gestational HT or HT with subclinical hypertension-mediated organ damage (BP threshold ≥ 140/≥ 90 mm Hg). The majority of studies (almost 50 studies) conducted to date, including Control of Hypertension in Pregnancy Study (CHIPS) described below, which evaluated the efficacy and safety of antihypertensive drug treatment in pregnancy, assumed the diastolic BP threshold of ≥ 90 mm Hg for the initiation of antihypertensive drug treatment. Fewer studies used systolic blood pressure thresholds for the initiation of antihypertensive treatment with the systolic BP threshold of ≥ 140 mm Hg (Fig. 5.5) assumed by the vast majority (almost 30) of them [64–66].

Patients with systolic BP ≥ 160 mm Hg or diastolic BP ≥ 110 mm Hg obtained in multiple consecutive measurements taken within 15–30 minutes are considered a hypertensive emergency and a hospital referral is recommended. Antihypertensive treatment in such patients should be initiated within 60 minutes (see Chapter 5.8) [14].

The ESC guidelines consider an SBP ≥ 170 mm Hg or DBP ≥ 110 mm Hg an emergency in a pregnant woman. However, following the recommendations of gynaecological...
Figure 5.5. Principles of antihypertensive treatment in pregnancy. *Extended release formulation; **Do not combine metoprolol and labetalol
societies and the Regulation of the Minister of Health, we decided to assume a lower threshold for hypertensive emergency (SBP ≥ 160 mm Hg/DBP ≥ 110 mm Hg) [1, 5, 6, 14].

Overzealous blood pressure control should be avoided as it may lead to placental hypoperfusion and this will compromise the foetus.

To date, the only randomized study which evaluated the benefits of more or less “tight” BP control in pregnancy was the CHIPS study [65]. 987 women at 14- to 33-week gestation with nonproteinuric pre-existent or gestational HT, office DBP 90 to 105 mm Hg (or 85–105 mm Hg if on antihypertensives), and a live foetus were enrolled [65].

Patients were randomized to (1) less tight (target DBP 100 mm Hg) control, where antihypertensive treatment must be started or increased in dose if DBP was ≥ 105 mm Hg and decreased in dose or discontinued if DBP was < 100 mm Hg or (2) tight control (target DBP 85 mm Hg) where antihypertensive treatment must be started or increased in dose if DBP was > 85 mm Hg and decreased in dose or discontinued if DBP was ≤ 80 mm Hg [65].

The composite primary endpoint was pregnancy loss or high-level neonatal care for > 48 hours in the first 28 days of life. The secondary endpoint was maternal death or serious maternal complications before 6 weeks postpartum. The BP achieved in tight control was 133.1 systolic and 85.3 mm Hg diastolic, as compared to less tight control with 138.8 mm Hg systolic and 89.9 mm Hg diastolic. Thus, the mean between-group difference was 5.8 mm Hg systolic and 4.6 mm Hg diastolic (p < 0.001 for both comparisons). There was no impact of less tight versus tight control on perinatal death or high-level neonatal care for > 48 hours (31.4% vs. 30.7%, respectively) or serious maternal complications (3.7% vs. 2.0%, respectively). However, there was more severe maternal HT in less tight vs. tight control group (40.6% and 27.5%, respectively; p < 0.001) [65].

Subsequently, in the post-hoc analysis of CHIPS study data, an association between severe HT and a higher incidence of maternal and neonatal complications was assessed. It was shown that severe maternal HT was associated with higher preterm birth rate, higher incidence of HELLP syndrome (haemolysis, elevated liver enzymes, low platelet count), as well as with lower birth weight. However, this association was only observed in the less-tight control group [67].

Subsequent exploratory analysis of the CHIPS data aimed to determine whether less-tight BP control (vs. tight control) affects perinatal and maternal outcomes. A tight BP control (vs. less-tight control) before 24 gestational weeks was associated with a higher risk of birth weight < 10th percentile as well as a lower risk of delivery < 37 weeks and of severe maternal HT, particularly so when women were randomized before 28 weeks [68].

Notably, the CHIPS remains the only randomized study published to date, which evaluated the benefits of more or less “tight” BP control in pregnancy. Good BP control (mean BP <140/90 mm Hg) was achieved in both groups. Tight control (DBP of 81–85 mm Hg) was associated with a lower rate of severe maternal HT. Development of severe HT was associated with more adverse perinatal and maternal outcomes. Tight BP control (vs. less-tight control) was associated with lower preterm birth rates and lower incidence of severe maternal HT at the expense of lower birth weight. The conclusion following the CHIPS was that tight control is the preferred management strategy in the second and third trimester (women in the first trimester were excluded from the study) [65, 67, 68].

Based on the CHIPS data, it was concluded that the diastolic BP target in pregnancy should fall in the range of 81–85 mm Hg [65, 67, 68]. However, there are no studies to evaluate the optimum target SBP range. The latest International Society for the Study of Hypertension in Pregnancy (ISSHP) guidelines recommend the range of 110–139 mmHg as the target SBP [1]. We consider it appropriate to assume the same range of target SBP values in antihypertensive treatment in pregnant women.

If SBP is < 110 mm Hg or DBP is ≤ 80 mm Hg, treatment de-escalation should be considered, whereas if SBP is > 140 mm Hg or DBP is > 85 mm Hg, treatment escalation is recommended.

It should be noted that the above target BP is primarily applicable to the second and third trimester. However, we consider it appropriate that the same thresholds apply to women in the first trimester. Only a few studies assessed the effect of antihypertensive treatment in the first trimester. Nzelu et al. conducted a prospective study in 586 pregnant women with chronic HT. The patients were subdivided at a median of 10 gestational weeks into group 1, with blood pressure < 140/90 mm Hg without antihypertensive medication, group 2, with blood pressure < 140/90 mm Hg with antihypertensive medication and group 3, with systolic blood pressure > 140 mm Hg and/or diastolic blood pressure > 90 mm Hg despite antihypertensive medication. In group 3, there was a significantly higher incidence of severe HT, preterm PE with onset at < 37 weeks of gestation and IUGR than in group 1. In group 2, the incidence of these outcome measures was non-significantly higher than in group 1 and lower than in group 3 [69]. On the other hand, the analysis of the German pharmacovigilance database showed that the exposure to methyldopa in the first trimester was associated with a higher incidence of adverse maternal and perinatal outcomes. However, the outcome analysis in that study did not control for the effect of blood pressure values [70]. The results of both studies support the conclusion that the need for antihypertensive treatment in the first trimester (when blood
pressure tends to decrease physiologically) may indicate higher severity of HT and the associated increased risk of maternal and perinatal complications. Thus, we believe, that BP reduction to the target values discussed above may be considered in the first trimester. However, as the BP physiologically decreases the first trimester, also in patients with chronic HT, dose reduction or even discontinuation of antihypertensive treatment may be considered in the first trimester provided that meticulous BP monitoring is continued (with BP of 110–139/81–85 mm Hg).

5.7.3. Antihypertensive drug treatment in pregnancy

Most studies evaluating the efficacy and safety of individual antihypertensive drugs in pregnancy were conducted in the 1980s and 1990s. Only a dozen or so studies, including the CHIPS, were conducted within the first two decades of the 21st century. The most commonly assessed drugs were methyldopa, labetalol and nifedipine, which were used in over 3 thousand women. They were compared with placebo, no intervention and other antihypertensive drugs (including comparisons between the three abovementioned medications). Other antihypertensive drugs were studied less extensively. Metoprolol, verapamil and clonidine were evaluated in 4, 4 and 3 studies respectively, in approximately 450 women altogether. Prazosin, isradipine, ketanserin, hydralazine and β-blockers: atenolol, oxprenolol and mapindolol were also used in more than one study. Acebutolol, amlodipine, bisoprolol, furosemide, nitrendipine and propranolol were evaluated in single studies in small samples each. Such a large difference between the number of studies and sample sizes between methyldopa, labetalol and nifedipine compared to other antihypertensive drugs supports their use as preferred treatment of HT in pregnant women (Fig. 5.5) [14, 64–66].

Methyldopa, a centrally active sympatholytic agent (an antagonist to the α2 adrenergic receptor), has long been used in the treatment of HT in pregnancy and has an established safety record with a 7-year follow-up of child development following in utero exposure [71]. It can be used in pregnancy from the first trimester [70]. However, sedative effect and excessive sleepiness, as well as potential hepatotoxicity (usually transient elevation of liver function markers) limit its use. Other adverse effects of methyldopa include sodium and water retention, dry mouth, impaired sleep and fatigue. Dosage: 250 mg 2–3 times a day p.o., up to a daily dose of 2 g (max daily dose of 3 g) [14].

Labetalol is a selective α1-adrenergic and nonselective β-adrenergic receptor antagonist, which is not cardioselective and does not have intrinsic sympathomimetic activity. This drug is considered to provide effective BP control and to be safe in pregnancy. Labetalol was also the recommended antihypertensive of the first choice in the CHIPS study [65, 72, 73]. Recommendations of different medical societies unequivocally recommend labetalol, alongside methyldopa and extended-release nifedipine, as antihypertensive of the first choice in HT in pregnant women [2, 4, 9]. Dosage: 100 mg twice a day p.o., up to a daily dose of 800 mg (maximum daily dose of 1200 mg divided into 2–4 doses). Importantly, as labetalol may be associated with the risk of maternal and foetal bradycardia, it should not be used in women with impaired left ventricular systolic function, high-grade atioventricular block and asthma [14].

It has been emphasized that all β-blockers (including labetalol) used in pregnancy may be associated with the risk of bradycardia, hypoglycaemia and IUGR (especially following the exposure in the first trimester) [74–77]. Recent ESC guidelines does not explicitly address recommending β-blockers other than labetalol in pregnant women, only stating that atenolol should be ‘best avoided’, and that ‘β-adrenergic blocking agents are generally safe in pregnancy’ (mainly as antiarrhythmic drugs), while β-1-selective drugs (e.g. metoprolol) are preferred [2]. Out of four studies evaluating metoprolol in pregnant women with HT, three used metoprolol tartrate and one metoprolol succinate [64, 66]. It should be noted, though, that metoprolol succinate has more approved indications, including functional arrhythmias. Therefore, extended-release metoprolol succinate may be considered in women with HT and sinus tachycardia/heart palpitations, provided that foetal growth is carefully monitored for the potential adverse effect of treatment.

Calcium channel blockers are a class of antihypertensive drugs with a favourable safety profile in pregnancy, which are currently listed as pregnancy class I drugs in HT [2, 4, 67]. Out of this drug class, extended release nifedipine has been most commonly used and studied in pregnancy [78–80]. Other dihydropyridine derivatives (L-type calcium channel blockers), namely, nicardipine [81], amlodipine [82], nitrendipine [83, 84] or isradipine [85] were only evaluated in single studies or used in a small number of pregnant women in database analyses [86, 87]. Thus, there is not enough data to draw conclusions regarding their safety in pregnancy. Extended-release nifedipine is, therefore, antihypertensive of the first choice alongside methyldopa and labetalol. Some experts propose a class effect approach to using calcium channel blockers in pregnant women, i.e. that there are no premises to anticipate the adverse effect of, for example, amlodipine or nitrendipine in pregnancy, as there is no evidence to support such effect of nifedipine. However, the published guidelines have not shared this view to date. The 2018 ESC guidelines state that ‘calcium antagonists are the drugs of choice’ indicating that ‘most data is available for nifedipine’ [2]. The combined treatment with calcium channel blockers and magnesium sulphate may be associated with a significant BP reduction due to their potential synergism [88]. The recommended daily dose of extended-release nifedipine ranges from 30 mg to 120 mg.
p.o. The most common adverse effects of nifedipine include excessive blood pressure lowering, headaches, dizziness, flushing and peripheral oedema.

**Verapamil**, a non-dihydropyridine calcium channel blocker, was used in pregnant women, especially those with arrhythmia, in a few studies [89, 90]. There is no sufficient data regarding its maternal and foetal side-effects. However, possible tocolytic effect and interaction with magnesium sulphate have been pointed out [88]. Verapamil is referred to in the ESC guidelines as ‘fairly safe during pregnancy’, although mainly indicated for the treatment and prevention of arrhythmias [4]. Dosage: daily dose up to 120 mg p.o. Adverse effects of verapamil include first-, second- and third-degree atrioventricular block, bradycardia, dizziness, headaches, persistent constipation, and flushing.

Metoprolol or verapamil may be considered in women who do not respond or tolerate methyldopa, labetalol and extended-release nifedipine. Labetalol should not be used in combination with metoprolol or verapamil, whereas metoprolol should not be used in combination with verapamil.

Other antihypertensives, the safety and efficacy of which have been evaluated in a limited number of studies, are clonidine, hydralazine and prazosin.

**Clonidine** is a centrally active sympatholytic agent that stimulates α-2 adrenergic receptors and, to a lesser extent, imidazoline receptors. The safety of clonidine in pregnancy has been assessed in several studies. Due to similar mechanisms of action, it should not be combined with methyldopa. The most common adverse effects include drowsiness, dry mouth and reduced cognitive performance [14].

**Hydralazine** is a vasoconstrictor used in the treatment of severe HT in pregnant women. Its efficacy and safety have been assessed in several studies, including hypertensive emergencies. The most common adverse effects of hydralazine are a lupus-like syndrome, palpitations, headaches and flushing. It is not available in Poland [1–8].

**Alpha-blockers** act as antagonists on α1-adrenergic receptors located in smooth muscle cells of blood vessels. Individual substances have variable selectivity for α1 and α2 receptors and are quite well tolerated. Prazosin is the only α-blocker evaluated for safety and efficacy in pregnancy [64, 66]. Orthostatic hypotension, especially after the first dose, is one of the most common adverse effects.

Due to their teratogenicity, angiotensin-converting enzyme ACE inhibitors (ACEI) are contraindicated during pregnancy [75, 91–93]. The same applies to renin inhibitors and angiotensin II-receptor blockers/neprilysin inhibitors [2, 75]. Diltiazem should also not be used during pregnancy. Treatment continuation with diuretics started pre-conception is controversial. We do not recommend diuretics in pregnancy due to possible oligohydramnios and foetal electrolyte imbalance [75]. Spironolactone has been shown to adversely affect foetal development in animal studies (using MRAs in pregnant women is discussed in Chapter 7.2).

Labetalol and extended-release nifedipine are only available in Poland through direct import, which requires completing a relevant application, according to the instructions available on the website of the Ministry of Health, Department of Drug Policy and Pharmacy (www2.mz.gov.pl/wwwwmz/index).

### 5.7.4. Combined treatment of hypertension in pregnancy

The results of studies conducted to date show that monotherapy offers good blood pressure control in the majority of pregnant patients with HT. In the CHIPS study, combined treatment was used in about 35% and 30% of women in tight and less-tight control groups, respectively [94]. As shown in Figure 5.5, if monotherapy proves ineffective, combined treatment with two drugs, followed by three drugs (a preferred combination of methyldopa, labetalol and extended-release nifedipine) should be used. The standard definition of refractory HT does not apply to pregnancy. With uncontrolled BP despite 3 antihypertensive drugs, out-of-office BP measurements should be used to verify the condition. If a failure to control BP despite 3 antihypertensive drugs is confirmed, the patient should be referred to a specialist centre with expertise in the diagnosis and treatment of HT during pregnancy.

### 5.8. Management of hypertensive emergency

Treatment of hypertensive emergencies is one of the most difficult and widely debated issues in the treatment of pregnant women. Despite the effort of many renowned medical centres, medical societies and organisations worldwide, treatment recommendations are still discrepant with no uniform treatment algorithm [1, 2, 4, 8, 95]. In the absence of large, multi-centre, randomized trials in pregnant women with HT, it is difficult to develop universal recommendations. The principles presented below are based on the analysis of available studies and guidelines [1, 2, 4, 8, 9, 95].

The following principles should inform the treatment of hypertensive emergency:

- Reliable blood pressure measurements (see Chapter 5.1) must be ensured.
- In patients with SBP ≥ 160 mm Hg and/or DBP ≥ 110 mm Hg as well as those with eclampsia or PE (see Chapter 6.2.3) even with lower blood pressure values, hospital referral needs to be made [1].
- Regardless of concomitant complications of HT in pregnancy, any patient with blood pressure ≥ 160/110 mm Hg requires treatment as a hypertensive emergency.
- In a patient with high BP values and in whom hospitalization is recommended in case of prolonged transport to the hospital one of the drugs recommended in hypertensive emergencies may be considered (Tab. 5.5).
BP values should be closely monitored (reduction in BP values should not delay hospitalization).

- Blood pressure reduction should be monitored, preferably with direct arterial blood pressure (DABP) monitoring. Antihypertensive treatment in a hypertensive emergency should aim at a 25% reduction in the mean arterial blood pressure, followed by a further blood pressure reduction to < 160/110 mm Hg within minutes/hours [8]. Too rapid blood pressure lowering may cause serious maternal and foetal complications. In hypertensive urgencies, blood pressure lowering should be achieved within hours/days.

- In women with severe HT, the intensive antihypertensive treatment aims at achieving BP < 160/110 mm Hg [8]. Once the BP values have stabilized, long-term treatment with oral antihypertensives should be started with the aim to achieve target BP (110–140 mm Hg/80–85 mm Hg) within a few consecutive days (see Chapter 5.7).

- Diastolic blood pressure reduction to < 80 mm Hg is an indication for dose reduction or discontinuation of antihypertensive treatment [1].

- Treatment of hypertensive emergency should include close monitoring of maternal and foetal vital signs. Alongside blood pressure measurements, maternal heart rate, respiratory rate, oxygen saturation, temperature, hourly diuresis, fluid balance and neurological condition (even every hour) should be monitored. Early diagnosis of target organ damage, including regular screening for proteinuria, is a vital component of maternal surveillance. In patients with PE, laboratory tests should be performed at least every 12 h, and even every 4–8 h with significant haematological and/or biochemical abnormalities and haemorrhagic complications [96]. In patients with PE, diagnosis and monitoring of target-organ damage are crucial in assessing the indications for delivery. Monitoring foetal vital signs and development is another essential factor to inform clinical decision-making about delivery (see Chapter 6.3).

- Antihypertensive drugs used for the treatment of severe HT (Tab. 5.5 and 5.6) share the following common characteristics:

### Antihypertensive Treatment in Pregnancy — Summary

| Smoking cessation and alcohol abstinence are recommended in pregnant and breastfeeding women | Level C |
| Achieving optimum body weight prior to conception is recommended | Level B |
| The daily recommended water intake in the second/third trimester and during breastfeeding is 3 litres and 3.8 litres, respectively. | Level B |
| The daily recommended water intake in the first trimester is 2.7 litres | Level C |
| A balanced, varied and healthy diet is recommended in pregnancy | Level C |
| Moderate physical activity is recommended in pregnant women who regularly exercised prior to conception | Level C |
| The recommended blood pressure thresholds for the initiation of antihypertensive treatment are SBP ≥ 140 mm Hg and/or DBP ≥ 90 mm Hg | Level B |
| The recommended blood pressure targets in pregnancy are 110–139 mm Hg systolic and 81–85 mm Hg diastolic | Level C |
| Hospital referral is recommended in patients with SBP ≥ 160 mm Hg and/or DBP ≥ 110 mm Hg | Level C |
| Methyldopa, labetalol and extended-release nifedipine are antihypertensives of the first choice in pregnant women with HT | Level B |
| In women with indications for treatment with cardioselective β-blockers, metoprolol should be considered | Level C |
| Diuretics and spironolactone are not recommended as antihypertensives in pregnancy (except in special circumstances) | Level C |
| Angiotensin-converting enzyme inhibitors, angiotensin II-receptor blockers, renin inhibitors and diltiazem are not recommended as antihypertensive treatment in pregnancy (except in special circumstances) | Level C |

### Management of Hypertensive Emergency — Recommendations

| Emergency inpatient admission and treatment of hypertensive emergency are indicated in pregnant women with SBP ≥ 160 mm Hg and/or DBP ≥ 110 mm Hg | Level C |
| Inpatient admission is recommended in pregnant women with PE or symptoms of PE, regardless of their blood pressure | Level C |
| Antihypertensive medications recommended for treatment of hypertensive emergencies include labetalol i.v., nifedipine p.o. and hydralazine i.v. | Level C |
| The 25% reduction in the mean arterial blood pressure, followed by a further blood pressure reduction to < 160/110 mm Hg within minutes/hours is recommended in hypertensive emergency | Level C |
| Labetalol, in both intravenous and oral formulations, is not approved in Poland. It is only available through direct import. We recommend ensuring appropriate stock, e.g. amount sufficient for the treatment of 1–2 patients, for the immediate needs of the ward | Level C |
— high efficacy and rate of blood pressure reduction;
— low risk of a maternal and perinatal adverse effect;
— option for parenteral administration;
— availability at the clinic/hospital ‘the medication is waiting for the patient’.

• All clinics/hospitals providing care of pregnant women should have a clear antihypertensive treatment algorithm with efficacy assessment and recommended rate of blood pressure reduction, as well as a form to document actions taken and their effect.

• Magnesium sulphate should be administered for neuroprotection before 32 gestational weeks. The indications are summarised in Table 5.7.

• A possibility to immediately end the pregnancy in selected situations (see Chapter 6.3) should be available.

• Treatment of multi-organ complications, ideally by the multidisciplinary team including consultant gynaecologist-obstetrician, consultant cardiologist, clinical hypertension specialist, consultant anaesthesiologist, consultant neonatologist, consultant neurologist and consultant nephrologist, should be possible.

• Furosemide (and other loop diuretics) are not recommended in PE due to plasma volume reduction. They should only potentially be used for the treatment of pulmonary oedema [8].

• In order to avoid pulmonary oedema, the intravenous and oral fluid intake should be limited in patients with PE [8].

6. MANAGEMENT OF PREGNANCY-INDUCED HYPERTENSION AND PRE-ECLAMPSIA

6.1. Pathogenesis of pregnancy-induced hypertension and pre-eclampsia

The pathogenesis of gestational HT or PE has not been fully explained to date. It seems that abnormal placentation...
and increased release of biologically active placental factors causing endothelial dysfunction, systemic inflammatory response and coagulopathy may be associated with genetic, environmental and perhaps also dietary factors. However, the most common view is that PE develops secondary to abnormal trophoblast invasion, which under physiological conditions leads to spiral artery remodelling [97]. Physiologically, human extravillous trophoblasts penetrate decidual veins and lymphatics before remodelling spiral arteries during early pregnancy. As a result, the luminal diameter of spiral arteries increases, and they become unresponsive to vasoconstrictive agents, which leads to increased uteroplacental blood flow [98]. The luminal diameter of spiral arteries increases several times as compared to its size before conception. The development of uteroplacental circulation ensures normal intervillous space perfusion. In the early stage of pre-eclampsia, trophoblastic cells only invade the intradecidual portion of the spiral arteries, without the remodelling of myometrial segments of the spiral arteries. Furthermore, patients with PE have fewer spiral arteries and their luminal diameter is halved as compared to normal pregnancy [99]. One of its consequences is reduced uteroplacental blood flow. In a normal pregnancy, the placental vascular bed is a low-resistance circulation. Therefore, abnormal trophoblast invasion, leading to high-resistance placental blood flow, is thought to be the underlying cause of pre-eclampsia. Thus, the processes responsible for the development of PE occur very early in pregnancy. In such situations, the pregnancy seems to develop normally in the first trimester and there is no clear tell-tale sign of upcoming complications.

Following the onset of PE, delivery regardless of gestational age is the only known effective treatment in many cases. A number of biologically active placental factors have been identified. In a normal pregnancy, a balance between pro- and antiangiogenic factors is maintained. The vascular endothelial growth factor (VEGF), the placental growth factor (PlGF) and the transforming growth factor β (TGF-β) are the key proangiogenic factors, whereas the soluble fms-
like tyrosine kinase-1 (sFlt 1) and soluble TGF-β coreceptor, endoglin (sEng), are the key antiangiogenic factors. In PE, both hypoxia and oxidative stress result in a decreased production of vasodilators, VEGF and PlGF, and a simultaneous upregulated release of their antagonists, sFlt 1 and sEng [100]. The increased blood pressure is a direct consequence of the imbalance between vasodilation and vasoconstriction, and the subsequently triggered inflammatory response. Patients with PE have lower levels of pregnancy-associated plasma protein (PAPP-A) [101]. Furthermore, agonistic autoantibodies against the angiotensin II type 1 receptor (AT1) and upregulated expression of AT1 receptor in the placenta have also been described in PE. An increase in many components of the circulating renin–angiotensin system (RAAS) seems to have a significant effect on blood pressure elevation, proteinuria and inflammatory cytokine stimulation. Based on the time of onset, clinical course and differences in foetal outcomes, early-onset PE and late-onset PE have been distinguished. The early-onset PE developing before 34 gestational weeks affects ~10% of cases and is often accompanied by intrauterine growth restriction and chronic foetal hypoxia, which may lead to intrauterine death. The early-onset PE is also associated with high dynamics of blood pressure elevation, proteinuria and maternal multiorgan complications. As a result, premature delivery is often necessary, because only this intervention can stop further damage and resolve the symptoms.

6.2. Risk assessment, prevention and diagnosis of pre-eclampsia

6.2.1. Assessing the risk of pre-eclampsia

The current state of medical knowledge makes it possible to identify women at high risk of pre-eclampsia. There are many factors that may modify the risk of PE. Their classification according to risk levels is shown in Table 6.1 [2].

Due to its multifactorial aetiology, risk assessment for PE based exclusively on medical history is insufficient. Therefore, the search for biophysical and biochemical markers to enable early identification of pregnant women at risk of pre-eclampsia later in pregnancy has continued for years. Currently, available screening is based on the combination of findings from medical history, biophysical assessments including ultrasonography and mean arterial pressure (MAP = \( \frac{1}{3} (SBP – DBP) + DBP \)), as well as biochemical methods (serum markers) (Fig. 6.1). According to the recommendation of the Foetal Medicine Foundation (FMF), BP should be measured simultaneously in both arms [102, 103].

Abnormal trophoblast invasion in early pregnancy leads to a reduction of uteroplacental blood flow, which increases in severity with gestational age. Increased vascular resistance in uteroplacental circulation can be detected with an ultrasound as early as in the first trimester (between 11th and 13th gestational weeks). The pulsatility index (PI) is then calculated for the right and left uterine artery. Abnormal placental perfusion, reflected in an elevated pulsatility index of uterine arteries, is considered one of the causes of PE. To calculate the pulsatility index (PI), it is necessary to determine the maximum systolic velocity (S), maximum diastolic velocity (D) and the mean flow velocity (Vmean). The pulsatility index is then calculated according to the formula: PI = (S – D)/Vmean. The higher vascular resistance, the lower maximum diastolic velocity and, in turn, the higher PI will be. High PI indicating persistently high vascular resistance in uterine arteries should be considered a symptom of abnormal placental circulation, which results in abnormal placental perfusion and subsequent development of PE. The validity of the uterine artery pulsatility index (PI) was confirmed in extensive meta-analyses, often in groups of over 50,000 patients [104–106]. PE screening based on the uterine artery resistance index was described in detail by Professor Kypros Nicolaides from the King’s College Hospital in London [107–109]. The pulsatility index is used for calculating the risk of PE in the algorithm developed by the Foetal Medicine Foundation, which is available online at https://foetalmedicine.org/research/assess/pre-eclampsia. The values of biochemical parameters, including a placental growth factor (PLGF) level, are also necessary for the calculation [110]. The calculation yields a number reflecting a specific risk for that individual patient. The FMF calculator also enables estimating the risk of intrauterine growth restriction. Risk of pre-eclampsia higher than 1:150 is usually considered an indication for aspirin prophylaxis. Screening based on risk factors, uterine artery flow parameters, MAP, as well as PAPP-A and PLGF levels enables identification of 95% of cases of early pre-eclampsia with a false positive rate of 10% [111]. The PE management algorithm based on risk stratification is shown in Figure 6.1.

There is an increasing body of evidence to support the ability to predict PE also later in pregnancy. One of the proposed models for predicting PE in the second trimester (between 19 and 24 gestational weeks) included parity, utero-

ine artery pulsatility index (PI), MAP, as well as plasma levels of PLGF and soluble fms-like tyrosine kinase 1 (sFlt-1) [112]. It has been demonstrated that sFlt-1 has a very high affinity to PLGF, VEGF-B and VEGF. In a normal pregnancy, PLGF and sFlt-1 are the prerequisites necessary for normal placental development. It has also been shown that in women with PE, the sFlt-1 level starts increasing from the second trimester, whereas the PLGF level starts decreasing at the end of the first trimester [113]. Importantly, this decrease in placental growth factor (PLGF) level and the increase in sFlt-1 level precede the onset of PE by even 5 weeks. The sFlt-1/PLGF ratio assessed between 20 and 35 gestational weeks is also a very useful predictor of pre-eclampsia. Within 4 weeks following the assessment, 80% of women with the sFlt-1/PLGF ratio above a derived cut-off developed PE, as compared to only 7% of those with the sFlt-1/PLGF ratio below a derived cut-off [113, 114]. The sFlt-1/PLGF ratio ≤ 38 virtually rules out the onset of PE within the next seven days [115, 116].

6.2.2. Prevention of pre-eclampsia

Early identification of patients at high risk of HT, weeks before the clinical onset, enables effective prevention. Meta-analyses of many randomized studies have shown that aspirin prophylaxis started before the 16 gestational weeks, i.e. before the uterine spiral artery remodelling ends, significantly reduces the risk of pre-eclampsia [117, 118]. The comprehensive, multicentre Aspirin versus Placebo in Pregnancies at High Risk for Preterm Pre-eclampsia (ASPRE) study confirmed that aspirin showed an 80% and a 63% reduction in the risk of developing PE < 34 weeks and < 37 weeks, respectively [119]. Although the mechanism of action of aspirin has not been fully understood to date, its direct effect on apoptosis and trophoblast proliferation as well as anticoagulant and antiplatelet effect preventing placental infarction have been proposed. Due to the high prevalence (up to 30%) of aspirin resistance found in studies that used aspirin doses below 100 mg, a 100–150 mg aspirin dose taken p.o. at bedtime is recommended [120]. Aspirin is undoubtedly the best prevention in women at high risk for preterm pre-eclampsia, identified using the risk calculation algorithm based on biophysical and biochemical parameters (Fig. 6.1). However, where individual risk assessment is not possible, aspirin prophylaxis should be considered in all patients with at least one high-risk factor or at least two moderate risk factors (Tab. 6.1).

6.2.3. Diagnosis of pre-eclampsia

Pre-eclampsia is a syndrome with multisystem involvement, which occurs after 20 weeks of gestation, peripartum or postpartum. It is primarily defined by the occurrence of new-onset HT plus new-onset proteinuria or HT and multisystemic signs in the absence of proteinuria. The diagnostic criteria of PE are shown in Table 6.2. In PE, peripheral vascular resistance and systemic arterial blood pressure are increased alongside a reduced plasma volume, unlike in a normal pregnancy. Proteinuria is currently included in the diagnostic criteria for PE, yet its presence is not required for the diagnosis. It is caused by the increased permeability of the glomerular filtration barrier or glomerular injury. During pregnancy, abnormal proteinuria is defined as urine protein excretion greater than 300 mg/24 h. In women with chronic HT, a stand-alone BP increase is not sufficient for the diagnosis of PE. The criteria for the diagnosis of superimposed PE include de novo onset of proteinuria and/or evidence of significant maternal organ or uteroplacental dysfunction after 20 gestational weeks. Furthermore, superimposed PE is diagnosed in women with persistent proteinuria who have sudden, substantial and sustained increases in protein excre-
PREVENTION OF PRE-ECLAMPSIA IN PREGNANT WOMEN WITH HYPERTENSION — RECOMMENDATIONS

A single 100–150 mg aspirin dose taken p.o. at bedtime is recommended in pregnant women with chronic HT. The treatment must be started before 16 gestational weeks and continued up to 36 gestational weeks. Where personalised risk assessment for PE is not possible, the decision to start aspirin prophylaxis should be made based on estimated risk. Aspirin prophylaxis as described above is recommended in women whose risk of PE is higher than 1:150. Level A

</table>
| • Proteinuria-induced hypertension developing after 20 gestational weeks coexisting with one or more of the following new onset conditions*:
  - Acute kidney injury (creatinine ≥ 1 mg/dL or ≥ 90 μmol/L)
  - Liver involvement (elevated transaminases, e.g. AST or ALT > 40 IU/L and/or severe right upper quadrant or epigastric pain)
  - Haematological complications (PLT count < 150,000/μL, DIC, haemolysis)
  - Neurological complications (e.g. eclampsia, altered mental status, amaurosis, stroke, clonus, severe headache, persistent visual scotomata)
  - Uteroplacental dysfunction (such as fetal growth restriction, abnormal umbilical artery Doppler wave form analysis, or stillbirth) |

*In patients with chronic hypertension, superimposed pre-eclampsia can be diagnosed based on the new onset of proteinuria or organ dysfunction (see the criteria above) after 20 gestational weeks. Superimposed pre-eclampsia cannot be diagnosed based on the rise in blood pressure or IUGR alone. In women with underlying chronic kidney disease manifesting as proteinuria, increased proteinuria alone is not sufficient to diagnose pre-eclampsia

6.3. Management of gestational hypertension and pre-eclampsia

In a normal pregnancy, a number of significant hemodynamic changes occur in the maternal cardiovascular system to ensure sufficient blood and nutrient supply to the foetus. Accelerated heart rate, increased plasma volume and cardiac output as well as reduced peripheral vascular resistance, resulting in a decreased arterial pressure, are mainly associated with upregulated endothelial activity and vasodilator release. Unfortunately, these adaptations during pregnancy are disturbed in one in ten women, usually during the second half of pregnancy [121]. In rare cases of abnormal trophoblastic proliferation, known as gestational trophoblastic disease, the onset of HT occurs already in the first half of pregnancy [122]. HT is more common and so is the onset before 20 gestational weeks in multiple gestation due to higher maternal physical stress and higher weight of the placenta(e) [121].

Pre-eclampsia, which affects about 2% of pregnant women, is the most severe hypertensive disorder in pregnancy [121]. Albeit fairly uncommon, it is one of the leading causes of maternal, foetal and neonatal mortality and morbidity. Pre-eclampsia may progress to eclampsia with stroke and seizures, life-threatening central nervous system conditions. Pregnancy-induced HT is also associated with other serious complications such as disseminated intravascular coagulation, liver damage, the HELLP (haemolysis, elevated liver enzymes, and low platelet count) syndrome or premature placental abruption.

Based on the time of onset, clinical course and differences in foetal outcomes, early-onset PE and late-onset PE have been distinguished. The early-onset PE developing before 34 gestational weeks affects approximately 10% of cases and is often accompanied by intrauterine growth restriction and chronic foetal hypoxia, which may lead to intrauterine death [123]. The early-onset PE is also associated with high dynamics of blood pressure elevation, proteinuria and maternal multi-organ complications. As a result, premature delivery is often necessary as the only means to stop further damage and resolve the symptoms. The SGA, preterm infants born to mothers with early-onset PE have a higher risk of neonatal complications, neurological disorder, as well as cardiovascular disease in adult life [121]. The late-onset PE mainly affects women with metabolic syndrome, obesity and gestational diabetes. The onset of BP elevation usually occurs near the term and the foetal size is normal, although foetal macrosomia is not uncommon. Multiple gestation is a risk factor. Excessive placental weight and suboptimal degradation rate of placental metabolic products seem to be the key contributors in these cases [123].

Unfortunately, even though both HT and other target organ complications resolve within the 6-week postpartum
period in most cases, these women continue to have an increased risk of gestational HT in subsequent pregnancies, as well as an increased risk of cardiovascular disease later in life.

Hypertension usually manifests clinically in the second half of pregnancy, leaving symptomatic treatment as the only treatment option, and delivery as the only curative treatment in severe cases. Therefore, it is vital that women at high-risk be identified and prophylaxis is started in the first trimester.

6.3.1. Management of gestational hypertension

With the new-onset BP elevation after 20 gestational weeks, the management should include the following:

- hospital referral in patients with SBP ≥ 160 mm Hg and/or DBP ≥ 110 mm Hg;
- monitoring and recording home blood pressure — 2 measurements in the morning and 2 measurements in the evening (Tab. 5.1);
- maternal biochemical blood and urine tests (Tab. 5.2);
- foetal ultrasound in order to assess foetal growth.

Outpatient monitoring can be considered in women with BP below 160/100 mm Hg, 24-hour urinary protein excretion of not more than 1 g, no other abnormal laboratory test findings and normal foetal growth. Hospital referral should be made in all other cases of PE.

Antihypertensive treatment with α-methyldopa or labetalol or extended release nifedipine should be initiated in women with uncomplicated gestational HT to achieve the target SBP of 110–140 mm Hg and the target DBP of 80–85 mm Hg. If BP control proves insufficient, a 24-hour BP monitoring and an assessment by the consultant cardiologist/clinical hypertension specialist should be requested (see Chapter 5.7.4) [124, 125].

Diuretics should not be used in women with pre-eclampsia and gestational hypertension, due to an increased risk of placental abruption.

Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin II-receptor blockers are contraindicated during pregnancy [126, 127].

Atenolol is not recommended during pregnancy due to its reported adverse effect on foetal growth [128].

In an outpatient setting, antenatal appointments in women with gestational HT should be scheduled at least every 2–4 weeks. Blood pressure, body weight, urinalysis and a full blood count should be assessed at each appointment, as well as a biochemistry panel in selected cases (Tab. 5.2, Fig. 6.2).

Foetal ultrasound for foetal growth assessment should be performed at least once every four weeks. The diagnosis of intrauterine growth restriction with abnormal blood flow parameters in uteroplacental and fetoplacental circulation is an indication for inpatient admission and intensive foetal wellbeing surveillance (Fig. 5.4)

In women with uncomplicated pregnancy-induced hypertension with no other concomitant maternal abnormality, normal laboratory test findings and normal foetal biometry, foetal wellbeing should be assessed with outpatient cardiotocography once a week from 36 gestational weeks onwards (Fig. 5.3).

Delivery in women with uncomplicated pregnancy-induced HT should be planned between 37 and 39 gestational weeks. The route and method of delivery should be determined based on obstetric factors and blood pressure values [129].

6.3.2. Management of pre-eclampsia

The diagnosis of PE is an indication for hospital referral and for the following actions to be taken (Fig. 6.3):

- maternal surveillance including:
  - blood pressure measurement at least 4 times a day,
  - monitoring diuresis and protein excretion in 24 hr urine collection,
  - assessing for other symptoms, such as headaches, vision impairment, abdominal pain, nausea and vomiting,
  - repeating laboratory blood tests (platelet count, liver function markers and plasma creatinine level) at least twice a week;
- in women with severe HT, the intensive antihypertensive treatment aims at achieving BP < 160/110 mm Hg [8]. Once the BP values have stabilized, long-term treatment with oral antihypertensives should be started with the aim to achieve target BP (110–140 mm Hg/80–85 mm Hg) within a few consecutive days (Chapter 5.7);
- if protein excretion in 24 hr urine collection is above 3.5 g, anticoagulant prophylaxis using low molecular weight heparins (LMWH) should be started;
- if a delivery before 32 gestational weeks is needed, magnesium sulphate should be administered in an intravenous infusion to prevent eclampsia and for foetal neuroprotection [130, 131];
- if a delivery before 34 gestational weeks is needed, a short (48-hour) course of antenatal glucocorticoid (betamethasone or dexamethasone in a total dose of 24 mg) therapy for foetal maturation should be administered [132];
- foetal wellbeing surveillance including:
  - foetal movement counting every day,
  - cardiotocography at least once a day,
  - foetal ultrasound for foetal growth assessment every 2 weeks,
  - additionally, if intrauterine growth restriction is confirmed, Doppler ultrasound should be performed in order to assess fetoplacental blood flow and biophysical profile of the foetus. Depending on the findings, it should be repeated at least once a week.
Figure 6.2. Perinatal care for women with gestational hypertension (HT) and pre-eclampsia (PE)

**Pregnancy-induced HT**
- After 20 gestational weeks, no proteinuria

**PE**
- Elevated BP and proteinuria after 20 gestational weeks or signs of organ damage without proteinuria (before 20 gestational weeks if trophoblastic gestational disease or multiple pregnancy)

**Chronic HT**
- Diagnosed pre-conception or before 20 gestational weeks, persists > 12 weeks postpartum

**Mild PE**
- BP 140/90–160/110 mm Hg
- daily proteinuria < 1 g
- normal foetal biometry

**Severe PE**
- BP ≥ 160/110 mm Hg
- increasing proteinuria
- PLT count < 100 000/mm³
- impaired liver function (elevated AST, ALT, LDH)
- persistent right subcostal or epigastric pain
- kidney failure
- pulmonary oedema
- CNS symptoms or vision impairment
- IUGR, oligohydramnios

**Outpatient surveillance**
- antihypertensive treatment: methyldopa/labetalol/nifedipine
- BP monitoring (home blood pressure diary — twice a day, 2 readings on each occasion)
- body weight control
- assessment of proteinuria, platelet count and liver enzymes (every 1–2 weeks)
- more frequent appointments depending on test findings
- foetal growth assessment, AFI
- foetal wellbeing: foetal movements, CTG, Doppler US (UA, MCA)

**Hospital management**
- tight BP control (at least 6 times a day or, alternatively, 24-hour BP monitoring)
- assessment of proteinuria
- body weight control daily, fluid balance monitoring daily
- laboratory tests (twice a week → every day)
- clinical assessment, including in particular: epigastric pain, headaches, vision impairment, increased deep tendon reflexes, impaired consciousness, dyspnoea or easy bruising and bleeding
- in severe PE — hourly urine output and pulse-oximetry
- CTG 1–3 times a day, Doppler ultrasound 1–2 times a week

**In all women PE, the pregnancy should not continue beyond 38 weeks of gestation**

**PE superimposed on chronic HT**
- Refer to a highly specialist centre

**ECLAMPSIA: HELLP SYNDROME**
- May occur in patients with PE during pregnancy or postpartum
### Management of Life-Threatening Emergencies in Pregnant Women with Hypertension

#### Severe Pre-eclampsia

**Pre-eclampsia**

Tonic-clonic seizure with loss of consciousness not preceded by PE in 40% of cases; classed as eclampsia if at least 2 of the following occur within the next 24 hours: HT, proteinuria, thrombocytopenia, elevated AST.

**Anticonvulsant therapy**
- Diazepam 10 mg i.v. (max. 30 mg)
- Magnesium sulphate (MgSO₄): 4–6 g i.v. within the first 30 minutes followed by an infusion at 1–2 g/h

**Immediate delivery** regardless of gestational age

**Postpartum**
- Aggressive treatment and monitoring
- Antihypertensive treatment — BP up to 150/100 mm Hg
- Eclamptic seizure prevention — magnesium sulphate (MgSO₄) i.v. infusion continued for 24–48 h
- Ensuring airway patency and good pulmonary ventilation, endotracheal suctioning, oxygen therapy
- Urine output monitoring
- Restoring electrolyte and acid-base balance
- Infection prevention and treatment
- Thrombosis prophylaxis

### Eclampsia

**Anticonvulsant therapy**
- Diazepam 10 mg i.v. (max. 30 mg)
- Magnesium sulphate (MgSO₄): 4–6 g i.v. within the first 30 minutes followed by an infusion at 1–2 g/h

**Immediate delivery** regardless of gestational age

**Postpartum**
- Aggressive treatment and monitoring
- Antihypertensive treatment — BP up to 150/100 mm Hg
- Eclamptic seizure prevention — magnesium sulphate (MgSO₄) i.v. infusion continued for 24–48 h
- Ensuring airway patency and good pulmonary ventilation, endotracheal suctioning, oxygen therapy
- Urine output monitoring
- Restoring electrolyte and acid-base balance
- Infection prevention and treatment
- Thrombosis prophylaxis

### HELLP Syndrome

- H — haemolysis: LDH ≥ 600 IU/L and/or bilirubin > 1.2 mg%
- EL — elevated liver enzymes: AST ≥ 70 IU/L
- LP — low platelets: PLT < 100 000/mm³

Hypertension is not an essential diagnostic criterion.

### 34–37 gestational weeks

- Delivery
  - Intrapartum, if clinically possible: magnesium sulphate (MgSO₄) (4–6 g i.v. within the first 30 minutes followed by an infusion at 1–2 g/h)

### 24–34 gestational weeks

- Conservative management with intensive maternal and foetal surveillance in a highly specialist perinatology centre
  - Course of steroids (24 mg/48 h — betamethasone)
  - Magnesium sulphate (MgSO₄) (4–6 g i.v. within the first 30 minutes followed by an infusion at 1 g/h continued for up to 24 h)
  - Emergency caesarean section on any maternal/foetal deterioration

### Before 24 gestational weeks

- The decision to end the pregnancy is made individually in each case; usually as soon as the mother is stable

### Delivery

- The delivery method should be determined based on the current maternal and foetal condition, gestational age, and cervical ripening

### Postpartum

- Aggressive treatment and monitoring
- Antihypertensive treatment — BP up to 150/100 mm Hg
- Eclamptic seizure prevention — magnesium sulphate (MgSO₄) i.v. infusion continued for 24–48 h
- Ensuring airway patency and good pulmonary ventilation, endotracheal suctioning, oxygen therapy
- Urine output monitoring
- Restoring electrolyte and acid-base balance
- Infection prevention and treatment
- Thrombosis prophylaxis

### After 34 gestational weeks

- Immediate delivery

### 27–34 gestational weeks

- Delivery within 48 hrs
  - Course of steroids (24 mg/48 h — betamethasone)
  - Magnesium sulphate (MgSO₄) (4–6 g i.v. within the first 30 minutes followed by an infusion at 1 g/h continued for up to 48 h)

### Before 27 gestational weeks

- The decision to end the pregnancy is made individually in each case; usually as soon as the mother is stable

### Delivery

- The delivery method should be determined based on the current maternal and foetal condition, gestational age, and cervical ripening

### Postpartum

- Aggressive treatment and monitoring
- Antihypertensive treatment — BP up to 150/100 mm Hg
- Eclamptic seizure prevention — magnesium sulphate (MgSO₄) i.v. infusion continued for 24–48 h
- Ensuring airway patency and good pulmonary ventilation, endotracheal suctioning, oxygen therapy
- Urine output monitoring
- Restoring electrolyte and acid-base balance
- Infection prevention and treatment
- Thrombosis prophylaxis

### Emergency delivery regardless of gestational age in the hospital where the patient has been admitted, upon the onset of:

- DIC
- Kidney failure
- Severe liver injury
- Premature placental abruption
- Biochemical marker deterioration
- Foetal deterioration

---

*Figure 6.3. Management of life-threatening emergencies in pregnant women with hypertension (HT)*
Timing of delivery in patients with pre-eclampsia should be determined on a number of factors including current maternal and foetal condition, gestational age, foetal position and cervical ripening.

Emergency delivery is indicated in women with pre-eclampsia:

- after 37 gestational weeks [133];
- before 37 gestational weeks, if:
  - the SBP is above 160 mm Hg systolic blood pressure and DBP is above 110 mm Hg, despite intensive antihypertensive treatment,
  - there is a significant liver or kidney function impairment, hemolysis, thrombocytopenia, and disseminated intravascular coagulation,
  - there is a new onset of eclampsia or other neurological symptoms including vision impairment and/or headaches,
  - there are symptoms suggestive of premature placental abruption,
  - there is a foetal life-threatening emergency,
  - there is intrauterine foetal death.

Intensive maternal surveillance and antihypertensive treatment should be continued postpartum for at least 48 hours, due to the risk of postpartum eclampsia.

### 7. PRECONCEPTION AND ANTENATAL MANAGEMENT OF SECONDARY HYPERTENSION AND SELECTED COMORBIDITIES

#### 7.1. Fibromuscular dysplasia

Fibromuscular dysplasia (FMD) typically affects renal arteries leading to HT. The second most common location is carotid and vertebral arteries. FMD can affect virtually any vascular bed. FMD affecting several vascular areas is not uncommon. FMD is also associated with a relatively high incidence of intracranial and abdominal aortic branches aneurysms [134–136]. The arterial walls of FMD-affected vessels are prone to dissection. Renal artery dissection may have detrimental clinical consequences, leading to the sudden onset of severe, refractory or malignant HT, acute kidney injury and renal infarction. Dissection of other arteries, including coronary, carotid and vertebral arteries, is also possible in patients with FMD [137–141]. The risk of PE in women with FMD is probably higher than in women without FMD, however, this data comes from one study in a small sample [142].

7.1.1. Definition of fibromuscular dysplasia

FMD is an idiopathic, segmental, non-inflammatory and non-atherosclerotic vascular disease leading to stenosis of small- and medium-sized arteries [136, 143].

7.1.2. Indications for the diagnosis of fibromuscular dysplasia

Patients with hypertension, especially women at reproductive age, should be assessed for renal artery stenosis secondary to FMD if any of the following indications are present [3]:

- rapidly progressing HT or a poor BP control in patients with previously well-controlled HT;
- stage 3 HT (≥ 180/110 mm Hg), accelerated hypertension or malignant HT;
- refractory HT;
- a small kidney in patients without known uropathy;
- abdominal murmur without obvious features of atherosclerosis;
- FMD affecting at least one other vascular bed;
- previous spontaneous artery dissection;
- family history of FMD;
- unexplained neurological incident.

According to the latest American-European consensus, screening for renal artery stenosis secondary to FMD should be considered in all women with HT planning to conceive [136]. It is our view that Doppler ultrasound of renal arteries should be performed in every woman at the reproductive age with HT. If FMD is found in renal arteries, the remaining vascular beds should be imaged to detect FMD and aneurysms [3, 136, 144].

7.1.3. Diagnosis of renal artery stenosis secondary to fibromuscular dysplasia

A screening test which can be performed in pregnant women is Doppler ultrasound of renal arteries. All findings...
positive for FMD and negative for FMD but in patients with significant clinical suspicion should be confirmed with another imaging investigation [3, 136]. Other diagnostic imaging of renal arteries with magnetic resonance angiography (MRA), computed tomography angiography (CTA) and digital subtraction angiography (DSA) is limited in pregnancy, which is discussed in detail in Chapter 5.8.

7.1.4. Treatment of renal artery stenosis secondary to fibromuscular dysplasia

If revascularisation procedure is indicated in women with HT and renal artery stenosis secondary to FMD, it should be performed prior to conception [3, 136]. Patients with HT after revascularisation or those without indications for revascularisation should be monitored clinically, with biochemical tests and diagnostic imaging. Doppler ultrasound of renal arteries should be performed in women after angioplasty due to renal artery stenosis secondary to FMD who plan to conceive in order to rule out restenosis [143].

Antihypertensive treatment in women with FMD should follow principles presented in Chapter 5.7. A 75–100 mg dose of aspirin is considered reasonable in women with FMD to prevent thrombotic and thromboembolic events [136]. The dose of aspirin should be increased in pregnant women with FMD and high risk of PE according to the principles outlined in Chapter 6.2.

7.1.5. Vascular complications in women with fibromuscular dysplasia

Each woman with FMD in one vascular bed should be assessed for the presence of FMD in other arteries. Endovascular or surgical treatment of stenosis and aneurysms, if indicated, is recommended prior to conception. Surgical treatment of renal or splenic artery aneurysms should be considered for aneurysms over 2 cm in diameter. Due to the risk of aneurysm rupture during pregnancy, the latest American-European consensus indicates that surgical treatment of aneurysms smaller than 2 cm should be considered in women planning to conceive [136].

A spontaneous coronary artery dissection occurs during or shortly after pregnancy in about 10% of cases, which has been discussed in Chapter 7.8.

7.2. Primary aldosteronism

7.2.1. Definition and prevalence

Primary aldosteronism (PA) is defined as endocrine HT caused by autonomous production of aldosterone. Based on this definition, primary aldosteronism is diagnosed by demonstrating that aldosterone levels in an individual are not affected by the factors, which physiologically mediate its secretion [145, 146]. The detailed guidance on the diagnosis and treatment of PA has been provided in the PTNT Recommendations of 2019 [3].

Pregnancy is associated with physiological changes to the activity of the RAAS [147–149]:
— increased synthesis of angiotensin;
— increased secretion of renin and angiotensin-converting enzyme;
— these changes lead to the increase in angiotensin II levels, which stimulates aldosterone secretion, resulting in elevated plasma aldosterone level, which can be up to 10-fold higher towards the end of pregnancy than at conception.

Despite aldosterone level elevation, its action is antagonized by a simultaneous significant increase in the levels of progesterone, a competitive inhibitor of aldosterone at the mineralocorticoid receptor [147–149].

Although PA is the most cause of secondary HT, the number of case reports published to date discussing challenges of the management of PA in pregnancy is relatively low. This may be due to the competitive effect of progesterone, which acts as a natural mineralocorticoid receptor antagonist, favourably affecting PA in pregnancy [147–149].

7.2.2. Clinical presentation

Clinical presentation of PA results from excessive autonomous aldosterone production and its effect on kidneys and the cardiovascular system. The key symptoms are presented in Table 4.2. There are only limited data regarding the clinical presentation of PA in pregnant women. Classical symptoms, such as hypokalaemia and dysregulated blood pressure predominate the clinical presentation [147–149].

Due to limited research data, it is impossible to develop recommendations regarding indications for the diagnostic assessment of PA in pregnant women, beyond those pre-

### MANAGEMENT OF FIBROMUSCULAR DYSPLASIA IN WOMEN AT REPRODUCTIVE AGE AND IN PREGNANCY — RECOMMENDATIONS

*In arteries other than renal
The determination of the aldosterone-to-renin ratio (ARR) should be considered in women with suspected PA and repeated testing for PA after pregnancy and breastfeeding. ARR may be normal in pregnant women with PA. Therefore, progesterone. However, it should be emphasized that the ARR indicates a stronger effect of aldosterone than the one of renin. Antihypertensive therapy should be modified and drugs which do not interfere with the renin–angiotensin–aldosterone system (RAAS) should only be used [145]. For the sake of a quick diagnosis, the ARR may be determined in pregnant women during antihypertensive treatment whilst considering the effect of treatment on renin and aldosterone levels. ARR is low in pregnant women due to a physiological upregulation of the renin–angiotensin–aldosterone system; renin levels are normal or elevated and aldosterone levels are elevated. Therefore, low renin concentration is the key prerequisite for the diagnosis of PA in pregnant women. This indicates a stronger effect of aldosterone than the one of progesterone. However, it should be emphasized that the ARR may be normal in pregnant women with PA. Therefore, repeated testing for PA after pregnancy and breastfeeding should be considered in women with suspected PA and normal ARR [147–149].

### 7.2.3. Screening for primary aldosteronism

The key screening for primary aldosteronism involves the determination of the aldosterone-to-renin ratio (ARR). When assessing and interpreting ARR, it is necessary to restore normal potassium levels in patients with hypokalaemia. Antihypertensive therapy should be modified and drugs which do not interfere with the renin–angiotensin–aldosterone system (RAAS) should only be used [145]. For the sake of a quick diagnosis, the ARR may be determined in pregnant women during antihypertensive treatment whilst considering the effect of treatment on renin and aldosterone levels. ARR is low in pregnant women due to a physiological upregulation of the renin–angiotensin–aldosterone system; renin levels are normal or elevated and aldosterone levels are elevated. Therefore, low renin concentration is the key prerequisite for the diagnosis of PA in pregnant women. This indicates a stronger effect of aldosterone than the one of progesterone. However, it should be emphasized that the ARR may be normal in pregnant women with PA. Therefore, repeated testing for PA after pregnancy and breastfeeding should be considered in women with suspected PA and normal ARR [147–149].

### 7.2.4. Confirming the diagnosis of primary aldosteronism

In Poland, the saline suppression test (SST) and the captopril challenge test (CCT) are the most commonly used to confirm the diagnosis of PA. In women at reproductive age, the assessment for PA, if indicated, should be done prior to conception. Confirming the diagnosis of PA in pregnancy is not recommended, due to a potentially harmful effect of hypervolemia during the saline suppression test and contraindications to the use of captopril [147–149].

### 7.2.5. Primary aldosteronism subtyping

Once the diagnosis of PA has been made based on clinical presentation and biochemical assays, the nature and location of adrenal lesions should be determined. The differential diagnosis should include bilateral adrenal hyperplasia and adrenocortical adenoma, the two main causes of PA. According to the guidelines, computed tomography and adrenal vein sampling should be performed as a part of PA subtyping [145, 150]. As neither of these can be performed in pregnancy, MRI may be considered to assess adrenal structure, but only in cases where surgical treatment is considered due to uncontrolled BP and potassium levels. In other cases, PA subtype should be determined after the delivery [147–149].

### 7.2.6. Treatment of primary aldosteronism

Surgical treatment is used in adrenocortical adenoma, whereas MRAs are recommended in patients with bilateral adrenal hyperplasia. The initial daily dose of spironolactone should be 12.5–25 mg administered in a single dose; the lowest effective dose should be determined by gradual daily dose adjustments up to 100 mg or more. Due to a possible teratogenic effect of spironolactone shown in animal studies (rats and rabbits, but not mice) and a possible feminising effect (by its direct action on androgen and progesterone receptors), spironolactone should not be used in pregnant women. It should be noted, however, that spironolactone has been commonly used for over 50 years and the number of its reported adverse effects in pregnancy is relatively low. There is one case report of ambiguous genitalia in the male foetus of a woman treated with spironolactone during early pregnancy, and a number of case reports, where spironolactone treatment in pregnancy was not associated with detrimental foetal outcomes. A potentially adverse effect of spironolactone-induced natriuresis on intrauterine growth has been postulated [2, 147–149].

Eplerenone is a newer, selective mineralocorticoid receptor antagonist, which has a lower antiandrogenic effect.

and a lower agonist effect on the progesterone receptor. Due to the shorter duration of action, eplerenone should be administered more often than once a day (starting from 25 mg twice a day) and in the dose twice as high as the one of spironolactone. However, eplerenone is not approved in the European Union for the treatment of primary aldosteronism. There is no evidence to support the adverse effect of eplerenone on the foetus. Furthermore, as mentioned above, eplerenone has no antiandrogenic effect. In the old FDA terminology, eplerenone had a pregnancy category B. Eplerenone may be considered in pregnant women with PA who have uncontrolled BP despite using other antihypertensives and/or uncontrolled potassium levels [2, 147]. Some experts do not share this view, pointing out that there is an insufficient body of evidence to support the recommendation of eplerenone, which also has limited approved indications. They recommend spironolactone after the second trimester in patients with uncontrolled BP [149].

However, the question of how to treat women with PA planning to conceive still remains unanswered. Replacing spironolactone with medications approved for use in pregnancy should be considered first, and when these prove ineffective, some experts suggest considering eplerenone [147–149].

Surgery should be performed in women at reproductive age with unilateral PA either before or after pregnancy. Surgery can only be considered in the second trimester, in women with unilateral adrenocortical adenoma and PA diagnosis confirmed with biochemical tests, in whom sufficient control of BP and potassium levels cannot be achieved with pharmacological treatment [147–149].

It should be noted that a sudden drop in progesterone levels may worsen the BP and potassium level control postpartum. Both spironolactone and eplerenone have been found in the breast milk of exposed mothers. Since the concentration of eplerenone in breast milk is believed to be negligible and too low to affect the infant, it should be considered in breastfeeding women who need antimineralocorticoid treatment, provided that the above limitations have been taken into account [147–149].

7.3. Catecholamine-secreting tumours

7.3.1. Definition

Catecholamine-secreting adrenal tumours are referred to as pheochromocytoma, whereas other chromaffin cell-derived tumours, which may also be hormonally active, located outside the adrenal glands, are referred to as paraganglioma. They are jointly referred to as the PPGL (pheochromocytoma and paraganglioma) [151].

The prevalence of PPGL in pregnancy is estimated at 1 in 54,000 pregnancies. Despite advances in medical knowledge and availability of contemporary diagnostic methods, a large number of PPGLs are still only detected during pregnancy. An undiagnosed PPGL poses a significant risk to both the mother and foetus. Early diagnosis in pregnancy and appropriate treatment reduce the maternal and foetal mortality to <5% and <15%, respectively [151–154].

Only a small portion of maternal catecholamines are transferred to foetal circulation. Furthermore, foetuses have high catecholamine clearance, which ensures their low levels in foetal circulation. Transient catecholamine peaks in women with PPGL may adversely affect the uteroplacental circulation causing vasoconstriction, which may lead to placental abruption and foetal hypoxia [151–154]. Antenatal care of women with PPGL should be provided by a multidisciplinary team with expertise and experience in the diagnosis and treatment of PPGL.

7.3.2. Clinical presentation

The proportion of noradrenaline to adrenaline secreted by PPGL determines its variable clinical presentation. The characteristic feature is paroxysmal symptoms, which may vary in severity and recur at variable intervals — as shown in Table 4.2. PPGL is most commonly symptomatic in pregnant women, and most patients (90%) experience symptoms before the delivery. PPGL should be suspected in pregnant women with refractory HT [152].

Physical exercise, abdominal compression, ample meals, some medications (ephephrine, phenylephrine, ACTH, pethoxazine, amphetamine, metoclopramide, tricyclic antidepressants, some anaesthetics), psychological stress and alcohol are known triggers. Catecholamine secretion from the tumour may also be induced by glucocorticoid administration. In pregnant women, symptom severity tends to increase with gestational age, as a result of tumour compression by the expanding uterus, foetal movements, uterine contractions and abdominal palpation. Pheochromocytoma may also be asymptomatic (including normotension) [151–156].

The maternal and foetal risk is the highest during the perinatal period in patients with PPGL. Both maternal and foetal morbidity and mortality were shown to be the highest in the perinatal period, especially in patients with undiagnosed PPGL. It is associated with labour, anaesthesia, abdominal palpation and perinatal medications, including metoclopramide. It should be noted that severe symptoms associated with sudden-onset, excessive catecholamine release from the tumour may occur within hours after the trigger [151–154].

7.3.3. Diagnosis of PPGL

Plasma or urinary fractionated metanephrines (normetanephrine and metanephrine measured separately) are the most useful and the most sensitive biochemical assays for PPGL, also in pregnant women. The determination of free
metanephrines levels in plasma offers the highest diagnostic sensitivity (sensitivity 97–99%, specificity 82%) [157]. The urinary adrenaline and noradrenaline excretion have a lower sensitivity and specificity, whereas vanillylmandelic acid (VMA) and dopamine levels in urine, as well as blood catecholamine levels, are considered the least useful [151, 152].

Plasma or urinary fractionated metanephrines are recommended in women at reproductive age with the history of PPGL resection both preconception and as soon as the pregnancy is confirmed.

Biochemical, anatomical and functional tests are recommended in female carriers of PPGL predisposing gene mutation at the reproductive age prior to conception in order to rule out PPGL.

7.3.4. Treatment of PPGL

Methyldopa and labetalol should not be used in pregnant women with PPGL, as they can aggravate the symptoms of PPGL and impair BP control. Furthermore, methyldopa may interfere with catecholamine metabolite assays [151–154].

The treatment of choice in catecholamine secreting PPGL is surgical resection. A surgical resection of abdominal catecholamine secreting PPGL in a pregnant woman may only be considered in the second trimester, before 24 gestational weeks [151–154]. In women with PPGL diagnosed after 24 gestational weeks, pharmacological treatment continued until the delivery may be considered. The elective resection can then be performed either as a combined procedure with the Caesarean section or after the delivery. The Caesarean section seems to be the preferred delivery method in women with catecholamine secreting PPGL, despite controversies due to limited evidence to support this recommendation. The timing and method of delivery should be determined individually for each patient by a multidisciplinary team [151–154].

Preoperative management, which should aim at lowering the BP and the heart rate as well as achieving the control of paroxysmal HT and other circulating catecholamine-induced symptoms, is a vital stage. For this purpose, α-blockers: phenoxybenzamine (in doses increased gradually from 10 mg two times a day to the maximum daily dose of 1 mg per body weight kg p.o. in 2–3 divided doses) or doxazosin (in doses increased gradually from 2 mg to the maximum daily dose of 32 mg p.o. in 1–2 divided doses) are used for 2–3 weeks prior to surgery. As phenoxybenzamine passes through the placenta, neonatal surveillance for hypotonia and respiratory failure is recommended during for the first few days after birth. About 1% of phenoxybenzamine passes to human breast milk. The FDA considers phenoxybenzamine the pregnancy category C drug. Due to its more favourable pharmacokinetic profile, shorter duration of action and competitive binding to α-adrenergic receptors, doxazosin seems to be a more preferred drug. It is also considered the pregnancy category C drug [151–154]. Furthermore, the use of phenoxybenzamine is restricted in Poland, as it is only available through the direct import route.

If an α-blocker seems ineffective, a calcium channel blocker (extended release nifedipine) can be added as the second antihypertensive drug. In patients with significant tachycardia, cardioselective β-blockers may be considered, but only after α blockers have been used. Catecholamines secreted by PPGL act on both α- and β-adrenergic receptors. Using β-blockers without prior administration of α-blockers is contraindicated as it poses a risk to upregulate α receptors, which may further increase the BP. Hypotonia should be avoided in antihypertensive treatment of women with hormonally active PPGL. As both phenoxybenzamine and doxazosin pass through the placenta, too aggressive BP lowering should be avoided (BP > 120/80 mm Hg) and foetal wellbeing surveillance continued throughout the treatment. As a part of preoperative management, it is important to address hypovolaemia by ensuring an adequate supply of sodium and fluids in order to avoid orthostatic hypotension [151–154].

Pregnant women with PPGL are at particularly high risk of hypertensive crisis due to the perinatal catecholamine

Coarctation of the aorta (CoA) accounts for 5–10% of all congenital heart defects. Despite the surgical correction, about 32.5% (25–68%) of patients with the history of CoA develop HT, with the rate depending on the treatment method and timing [158].

Even after successful surgery, patients with CoA have a moderate/high risk of cardiovascular disease in pregnancy, as per the modified WHO classification of maternal cardiovascular risk (mWHO II/III) [2]. Particular attention should be paid to patients with uncorrected CoA and those with persistent HT, residual CoA or aortic dilation. Bicuspid aortic valve in patients with CoA increases cardiovascular risk due to the risk of aortic dissection.

Coarctation of the aorta (CoA) accounts for 5–10% of all congenital heart defects. Despite the surgical correction, about 32.5% (25–68%) of patients with the history of CoA develop HT, with the rate depending on the treatment method and timing [158]. Patients with CoA generally tolerate pregnancy well. A higher incidence of PE and higher miscarriage rate were reported in pregnant women after a previous correction of CoA [2, 159, 160].

The ESC guidelines classify the corrected CoA as associated with a moderate mortality risk or a moderately high morbidity risk (mWHO II/III) and severe CoA in pregnancy (uncorrected or corrected) as associated with an extremely high risk of mortality or serious cardiovascular complications (mWHO IV) [2]. There are no published data regarding the optimum medical treatment of pregnant women with CoA and HT. Antihypertensive treatment as in the general population should be considered in pregnant women with HT whilst avoiding placental hypoperfusion [2]. Therefore, antenatal care of pregnant women with CoA and HT should be provided by multidisciplinary teams in a highly specialist centre.

### 7.4. Coarctation of the aorta

Coarctation of the aorta (CoA) accounts for 5–10% of all congenital heart defects. Despite the surgical correction, about 32.5% (25–68%) of patients with the history of CoA develop HT, with the rate depending on the treatment method and timing [158]. Patients with CoA generally tolerate pregnancy well. A higher incidence of PE and higher miscarriage rate were reported in pregnant women after a previous correction of CoA [2, 159, 160].

The ESC guidelines classify the corrected CoA as associated with a moderate mortality risk or a moderately high morbidity risk (mWHO II/III) and severe CoA in pregnancy (uncorrected or corrected) as associated with an extremely high risk of mortality or serious cardiovascular complications (mWHO IV) [2]. There are no published data regarding the optimum medical treatment of pregnant women with CoA and HT. Antihypertensive treatment as in the general population should be considered in pregnant women with HT whilst avoiding placental hypoperfusion [2]. Therefore, antenatal care of pregnant women with CoA and HT should be provided by multidisciplinary teams in a highly specialist centre.

### 7.5. Ascending aortic dilation

The management of Turner syndrome, Marfan syndrome and Ehlers-Danlos syndrome type 4 has been discussed in detail in the 2018 ESC guidelines [2]. Ascending aortic dilatation occurs most commonly in women with HT as a consequence of bicuspid aortic valve (BAV) or as a consequence of chronic HT.

#### 7.5.1. Bicuspid aortic valve

The most common site of ascending aortic dilatation in patients with BAV is above the sino-tubular junction (STJ). The risk of aortic dissection is low and depends on the diameter of the ascending aorta, aortic valve morphology and potential concomitant CoA [161]. Pregnancy is not recommended in patients with BAV and the diameter of the ascending aorta > 50 mm prior to the ascending aortic replacement [2]. CoA should be ruled out in women with BAV and HT.

#### 7.5.2. Management of ascending aortic dilation

Regular blood pressure monitoring is a key element of antenatal care. Monitoring the aortic diameter with echocardiography is necessary both throughout the pregnancy and up to 6 months postpartum. In women with significant aortic dilatation and a very high risk of aortic dissection, echocardiography should be performed every 12 weeks. If another imaging technique is necessary, plain (non-contrast) magnetic resonance imaging is recommended.

According to the ESC guidelines, treatment with β-blockers throughout the entire pregnancy should be considered in patients with ascending aortic dilatation secondary to congenital aortic anomalies (including BAV) [2].

| Antihypertensive treatment as in all pregnant women with HT should be considered in pregnant women with CoA and HT whilst avoiding placental hypoperfusion | Level C |
| Cardiac follow-up in normotensive pregnant patients after CoA correction should be scheduled once every trimester. However, in women with significant CoA, cardiac follow-up should be scheduled at least once a month | Level C |

In women with significant aortic dilation and a very high risk of aortic dissection, echocardiography should be performed once a month. Patients with low risk of aortic dissection and mild aortic dilation require echocardiographic assessment every 12 weeks | Level C |

| Treatment with β-blockers throughout the entire pregnancy should be considered in patients with ascending aortic dilation | Level C |

| In patients with the diameter of the aorta between 40–45 mm, vaginal delivery with spinal anaesthesia and a shortened second stage should be considered. Delivery by Caesarean section may be considered in women with the diameter of the aorta between 40–45 mm and should be considered in women with the diameter of the aorta > 45 mm | Level C |

| Pregnancy is not recommended in patients with BAV and the diameter of the ascending aorta > 50 mm | Level C |
Treatment with β-blockers started during pregnancy should also be continued postpartum. The delivery method should be determined based on the degree of ascending aortic dilation. In patients with the diameter of the aorta between 40–45 mm, vaginal delivery with spinal anaesthesia and a shortened second stage should be considered. Delivery by Caesarean section may be considered in women with the diameter of the aorta between 40–45 mm and should be considered in women with the diameter of the aorta > 45 mm [2].

7.6. Sleep disorder

Objective studies of human circadian rhythms clearly indicate that pregnancy is associated with impaired sleep quality, especially in the third trimester. Sleep in late gestation is significantly fragmented (cortical arousal and awakening), which results in a disarray of successive sleep stages, as well as shortened slow-wave and rapid eye movement (REM) sleep [162].

7.6.1. Epidemiology of sleep-disordered breathing in pregnancy

The incidence of sleep-disordered breathing (SDB) in women at reproductive age is the lowest in the general population of adult women and men [163]. The incidence of obstructive sleep apnoea (OSA) in pregnancy depends on gestational age. OSA is estimated to affect several per cent of pregnant women during the first trimester, as compared to almost 30% during the third trimester [164]. Diagnostic criteria of SDB assumed for adult populations also apply to pregnant women. Based on them, mild apnoea, defined as AHI (apnoea-hypopnea index, that is, the mean number of apnoea and hypopnea events per hour of sleep) of < 15 is diagnosed the most commonly [164].

7.6.2. Pathogenesis of obstructive sleep apnoea in pregnancy

It seems that hormone-dependent fluid retention is the key mechanism responsible for the increased risk of sleep apnoea in pregnant women. The direct consequence of hypervolemia is soft tissue oedema affecting the upper respiratory tract, which narrows the airway lumen [165–167].

7.6.3. Maternal and foetal complications of obstructive sleep apnoea

Patients with apnoea have an increased risk of gestational diabetes, pregnancy-induced HT and PE. As a result, preterm delivery is more likely in women with SDB. On the other hand, there is no clear evidence to suggest that untreated maternal sleep apnoea causes intrauterine growth restriction. However, it has been demonstrated that SDB in pregnant women is an independent risk factor for neonatal heart failure and respiratory failure (or cardiorespiratory arrest), which require postnatal resuscitation and/or neonatal intensive care [168, 169].

7.6.4. Diagnostic management, diagnostic criteria and classification of obstructive sleep apnoea in pregnancy

Diagnosis and assessing the severity of obstructive sleep apnoea should be based on objective evaluation with cardiorespiratory polygraphy or polysomnography [170, 171].

7.6.5. Treatment of obstructive sleep apnoea in pregnancy

The current guidelines do not recommend specific treatment of SDB in pregnant women. A few studies have shown partial efficacy of behavioural treatments in sleep apnoea including complete alcohol abstinence, a complete hypnotic and narcotic analgesic abstinence, and sleeping in a lateral decubitus position (which is also beneficial as it lessens the effect of inferior vena cava compression). However, weight loss is not recommended in obese pregnant women. Such interventions as mandibular advancement devices and the continuous positive airway pressure (CPAP) devices offer better efficacy.

7.7. Kidney disease
7.7.1. Chronic kidney disease

Chronic kidney disease (CKD) significantly increases the risk of HT in pregnant women [172]. HT affects about 20–50% of pregnant women with CKD and the prevalence of HT increases with the severity of CKD [173]. Data regarding distinctive pathophysiology of HT in pregnant women with kidney disease are derived from studies in experimental animals and studies in small groups of pregnant women with CKD. They point to the kidney maladaptation to pregnancy-induced physiological changes, which include about 50% increase in glomerular filtration, as the main cause of HT in pregnant women with CKD. As a result, sodium retention and hypervolemia occur, which lead to HT [174].

It can be assumed that, as it is true for the CKD in non-pregnant women, the pathogenesis of HT also involves hyperactivity of the sympathetic nervous system and the RAAS [175]. With the increasing severity of CKD, the risk of HT and associated maternal and foetal complications increas-
es. At the same time, maternal and perinatal outcomes are likely to be worse. PE, eclampsia, prematurity and low birth weight are more common in these women. Furthermore, neonatal intensive care is more likely to be required and the perinatal mortality rate is higher [177]. Bateman et al. found a higher risk of miscarriage, PE, IUGR and prematurity in women with CKD concomitant with HT than in women with normal BP during pregnancy [177].

The eGFR cannot be calculated in pregnant women with commonly used formulas, such as the MDRD (Modification of Diet in Renal Disease) formula or the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) formula [6]. Therefore, the severity of CKD in pregnant women is primarily based on the pre-conception eGFR values, whereas the clinical observation during pregnancy is based on the creatinine serum level measurements [178].

Upon a positive pregnancy test in a woman with CKD, it is necessary to assess the risk factors of maternal and foetal complications. It is necessary to determine the stage of kidney disease pre-conception, urinary protein (preferably albumin) excretion in 24hr urine collection, as well as serum levels of urea, creatinine, uric acid and glucose. Kidney function tests (serum levels of urea and creatinine), as well as urinary protein/albumin excretion assays, should be repeated at least once a month [176]. Tight BP monitoring (home blood pressure — 2 measurements in the morning and 2 measurements in the evening) is necessary for pregnant women with CKD. A 24-hour ambulatory blood pressure monitoring should also be considered [176].

Target BP in pregnant women with CKD is similar to the target BP in pregnant women without CKD, i.e. the target DBP in pregnant women with HT and CKD should be 81–85 mm Hg [65, 67, 68]. The choice of antihypertensive drugs in pregnant women with CKD should be informed by the same principles as in pregnant women without kidney disease. However, antihypertensive drugs with known nephroprotective effect recommended in non-pregnant women, such as ACEI, angiotensin receptor blockers and mineralocorticoid receptor antagonists, are prohibited in pregnant women with CKD. Since methyldopa is largely excreted by the kidneys, the Summary of Product Characteristics (SmPC) states that the dose should be reduced in patients with impaired renal function. It is recommended that with the eGFR between 60 and 89 mL/min/1.73 m² the interval between the doses be extended to 8 hours, with the eGFR between 30 and 59 mL/min/1.73 m² the interval between the doses be extended to 8–12 hours and with the eGFR < 30 mL/min/1.73 m² the interval between the doses be extended to 12–25 hours. Dialysis removes methyldopa; therefore, a booster dose of 250 mg is recommended to prevent blood pressure elevation after the procedure. As an exception, diuretics may be indicated in pregnant women with CKD (especially in advanced stages of the disease). Loop diuretics may be considered in very severe oedema, mainly secondary to nephrotic syndrome [30]. However, as the first line intervention in peripheral oedema, the patients should be advised to rest with their legs up and to use elastic stockings [172]. Diuretics are contraindicated in PE due to hypovolemia [175]. Pregnant women with CKD should be started on aspirin at a daily dose of 100–150 mg before 16 gestational weeks. This reduces the risk of PE, prematurity and intrauterine growth restriction [179]. Limited protein intake is not recommended in pregnant women with CKD, especially those on dialysis, whose daily protein intake should range between 1.5 and 1.8 g per body weight kg [175, 180]. However, there are no recommendations as to the salt intake in pregnant women with HT and CKD. Anaemia is a symptom of CKD, and may additionally increase in severity in pregnancy, due to a physiological increase in plasma volume, which is disproportionate in relation to other blood elements. It may also be associated with iron, vitamin B12 and folic acid deficiency [181]. Erythropoiesis-stimulating agents (ESAs) may be considered in pregnant women with CKD after normalising iron levels, initially with oral iron supplements [182]. Intravenous formulations are also safe in pregnant women, although one should bear in mind that they may cause an allergic reaction and stimulate uterine contrac-

| It is recommended to reduce the dose of methyldopa (by extending the interval between the doses) in pregnant women with an impaired renal function depending on the eGFR | Level C |
| Diuretics (especially loop diuretics) may be considered in patients with very severe oedema, mainly secondary to nephrotic syndrome | Level C |
| Starting aspirin treatment at a daily dose of 100–150 mg before 16 gestational weeks is recommended in pregnant women with CKD | Level C |
| Folic acid supplementation at a daily dose of 5 mg is recommended in pregnant women with CKD | Level C |
| Limited protein intake is not recommended in pregnant women with CKD | Level C |
| Maintaining haemoglobin levels within the range of 10–11 g/L is recommended in pregnant women with CKD | Level C |
| It is recommended to start renal replacement therapy (preferably haemodialysis) with maternal serum urea level of about 100 mg/dL (15 mmol/L). | Level C |
tions. Haemoglobin levels in pregnant women should be maintained within the range of 10–11 g/L. However, ESAs should be used with great caution in pregnant women, as they may contribute to the blood pressure increase, especially when the treatment was too aggressive and the haemoglobin level increased too rapidly or above the recommended value, i.e. 12 g/L [183].

Renal replacement therapy is an important treatment aspect in pregnant women with CKD, including those with concomitant HT. Further kidney function deterioration is seen in some patients with CKD during pregnancy. Indications for haemodialysis in a pregnant woman are determined based clinical assessment (e.g. hypervolemia resistant to medical management with the resulting HT) and the laboratory test findings (serum urea, potassium and bicarbonate levels). Elevated serum urea level is the most common indication for haemodialysis [181]. It is now believed that the haemodialysis should be started in pregnant women with serum urea level of about 100 mg/dL (15 mmol/L). The minimum duration of haemodialysis in patients with no residual diuresis, both those started on haemodialysis during pregnancy and those who have already been on haemodialysis at conception should be 36 hours/week. It is necessary to maintain serum urea levels of 60–90 mg/dL (10–15 mmol/L) prior to the next dialysis. Such intensive renal replacement therapy requires very tight electrolyte control (at least once a week) with potassium, magnesium, calcium and phosphorus supplementation. Using 1.5 mmol/L calcium dialysate is recommended. It is also advisable to supplement calcium and vitamin D [15]. Folic acid supplementation at a daily dose of 5 mg, multivitamin supplements as well as avoiding smoking and alcohol consumption are recommended from the beginning of pregnancy [175]. It is suggested not to start renal replacement therapy in pregnant women with peritoneal dialysis and to adopt a personalised approach in patients previously treated with peritoneal dialysis. The conversion to haemodialysis seems to be particularly indicated in patients with low residual diuresis, fluid retention tendency and multiple pregnancies [184]. In the light of reports of successful pregnancy outcomes in patients on peritoneal dialysis, peritoneal dialysis continuation can be considered in patients with significant residual diuresis [174].

7.8. Arrhythmia

7.8.1. Epidemiology

Palpitations and arrhythmia are common clinical problems in pregnant women, which do not require treatment in most cases [185]. The incidence of arrhythmia in pregnancy is closely linked to comorbidities. Supraventricular tachycardia occurs in 0.02 to 1.3% of pregnant women without structural heart disease. However, in women with congenital heart defects, ventricular and supraventricular arrhythmia, which require treatment may occur in 5–15% of patients [186–188]. Premature ventricular contractions (PVC) usually originating from the ventricular outflow tract occur in more than 50% of patients referred for 24-hour ECG registration due to heart palpitations. In most cases, they do not require antiarrhythmic treatment and usually resolve after delivery [189].

Alongside extrasystoles, atrial fibrillation (AF) and supraventricular tachycardia (SVT) are the most common arrhythmias in pregnant women [2]. The increased prevalence of AF is associated with maternal older age, HT, diabetes, obesity and congenital heart defects [185, 186].

7.8.2. Pathogenesis of arrhythmia in pregnancy

Pregnancy is associated with increased blood volume and cardiac output, which reach 150% of their baseline values around 32 gestational weeks. The increase in cardiac output in the first half of pregnancy is largely due to an increase in stroke volume and in the second half of pregnancy due to an increased heart rate.

Maternal cardiac rotation by 15–20 degrees to the left causes changes to the ST segment and the T wave. However, usually, there is no problem to confirm the sinus rhythm using the standard diagnostic criteria [2]. The heart rate of a pregnant woman increases by 10–15 beats per minute as compared to the non-pregnant state, which is a physiological phenomenon, but it may hinder the diagnosis of heart failure or pulmonary embolism.

Increased stress to the maternal heart can lead to arrhythmia, especially in patients with organic heart disease. The new onset of arrhythmia in pregnancy occurs in approximately 1/3 of affected pregnant women. Exacerbation of pre-existent arrhythmia in pregnancy occurs in another 30–40% of affected pregnant women [2]. Arrhythmia in pregnancy significantly increases the risk of gestational and perinatal complications and may lead to the development of foetal congenital anomalies [190].

7.8.3. Diagnosis of arrhythmia pre-conception and in pregnancy

The ESC guidelines recommend electrocardiography (ECG) and echocardiography as the minimum assessment possibly complemented with a stress test to assess the risk in women with a history of cardiac or aortic disease planning to conceive [186]. The same guidelines recommend the ECG Holter monitoring in pregnant women with palpitations, history of supraventricular and ventricular tachycardias as well as atrial fibrillation or flutter.

Women with arrhythmia present both pre-conception and in pregnancy should be actively assessed for congenital cardiomyopathy and channelopathies. Organic heart
The ESC guidelines recommend electrocardiography (ECG) and echocardiography as the minimum assessment possibly complemented with a stress test to assess the risk in women with a history of cardiac or aortic disease planning to conceive.

| The ESC guidelines recommend electrocardiography (ECG) and echocardiography as the minimum assessment possibly complemented with a stress test to assess the risk in women with a history of cardiac or aortic disease planning to conceive | Level C |
| The ECG Holter monitoring is recommended in pregnant women with a history of ventricular tachycardia, atrial fibrillation and/or flutter or heart palpitations | Level C |
| Consulting clinical data from Table 7 of the 2018 ESC guidelines, and should the information be missing, checking the online database www.safefoetus.com prior to starting pharmacological treatment of a pregnant woman | Level C |
| Beta-blockers are recommended during pregnancy and postpartum in women with long QT syndrome (LQTS) or catecholaminergic polymorphic ventricular tachycardia (CPVT) | Level C |
| Ablation guided by electroanatomical mapping in an experienced centre should be considered in women with poorly tolerated or refractory supraventricular tachycardia. Ablation should be at least considered in young women with paroxysmal arrhythmia (SVT, VT, AF) prior to conception. | Level C |
| Routine use of β-blockers in pregnant women with sinus tachycardia is not recommended, and ivabradine is contraindicated in pregnancy | Level C |
| Non-vitamin K oral anticoagulation drugs (apixaban, dabigatran, rivaroxaban) are contraindicated during pregnancy | Level C |

Whereas an emergency restoration of normal heart rhythm with cardioversion, intravenous administration of adenosine or a β-blocker is fairly safe for the foetus, long-term treatment with antiarrhythmic drugs to prevent arrhythmic episodes may pose a significant clinical problem [192].

The current European guidelines on the management of arrhythmias in pregnancy do not provide a clear treatment algorithm. The above guidelines do not recommend routine use of β-blockers in pregnant women with asymptomatic or even symptomatic sinus tachycardia. Considering the benefits and risks of β-blockers seems reasonable in pregnant women with symptomatic sinus tachycardia. It should be noted that ivabradine is contraindicated in pregnancy.

### 7.8.4. Treatment Sinus tachycardia

Sinus tachycardia is a frequent problem in pregnancy. TheESC experts have also proposed the scope of perinatal care and surveillance in patients with arrhythmias, based on their stratification to one of the three risk groups [186].

#### Emergency and long-term treatment

Whereas an emergency restoration of normal heart rhythm with cardioversion, intravenous administration of adenosine or a β-blocker is fairly safe for the foetus, long-term treatment with antiarrhythmic drugs to prevent arrhythmic episodes may pose a significant clinical problem [192].

The newest ESC guidelines clearly recommend consulting Table 7 of the 2018 ESC guidelines (‘Drug and safety data’), and should the information be missing, checking the online database www.safefoetus.com prior to starting pharmacological treatment of a pregnant woman.

It should be noted that non-vitamin K oral anticoagulation drugs are contraindicated during pregnancy [193].

Women with congenital long QT syndrome (LQTS) and catecholaminergic polymorphic ventricular tachycardia (CPVT) have a high risk of perinatal and postpartum arrhythmia, which can be reduced with β-blockers [194].

Ablation guided by electroanatomical mapping in an experienced centre should be considered in women with poorly tolerated or refractory supraventricular tachycardia. Ablation should be at least considered in young women with paroxysmal arrhythmia (SVT, VT, AF) prior to conception.

The detailed management of arrhythmias in pregnant women has been explained in the 2018 ESC Guidelines for the management of cardiovascular diseases during pregnancy [2] and in Figure 7.1 A–D.

### 7.9. Acute coronary syndromes

#### 7.9.1. Aetiology and epidemiology

The risk of myocardial infarction in pregnancy is 3–4 times higher than in age-matched non-pregnant women [2]. Risk factors include maternal age, HT, diabetes, obesity, smoking, hyperlipidaemia, eclampsia, multiple gestation, thrombophilia, cocaine misuse, and perinatal haemorrhage or infection [2]. Spontaneous coronary artery dissection (SCAD) is the most common cause of the prenatal and perinatal acute coronary syndrome. Less common findings are atherosclerosis, coronary artery thrombosis, normal coronary arteries or coronary vasospasm [195]. Relatively high rates of pregnancy-associated SCAD (P-SCAD) were reported in the past. The more recently reported prevalence of P-SCAD is about 10% of all spontaneous coronary artery dissections. In a large Canadian register of 4.4 million pregnant women, the prevalence rate of P-SCAD was estimated at 1.8 cases per 100,000 pregnancies [196].

#### 7.9.2. Pathogenesis

Two potential mechanisms of P-SCAD development are currently postulated: non-iatrogenic and non-traumatic intimal tear or spontaneous vasa vasorum rupture. In both mechanisms, intramural haemorrhage creates a false lumen and a separation of the coronary arterial wall, which narrows the true lumen and disturbs the blood flow [197, 198]. Based on the reported P-SCAD cases, potential mechanisms contributing to coronary artery dissection during pregnancy...
have been identified. These include increased cardiac output (secondary to increased blood volume and heart rate) and elevated progesterone and oestrogen levels leading to loss of normal corrugation of elastic fibres, impaired collagen synthesis and structural weakening of the vascular wall, especially the tunica media [199]. In a relatively high percentage of women with SCAD, FMD affects other vascular beds, as well. Therefore, extensive diagnostic investigation of FMD is necessary (see Chapter 7.1).

7.9.3. Patient characteristics and clinical presentation

P-SCAD typically occurs during the early postpartum and less frequently in the third trimester [200]. The clinical presentation of SCAD includes the symptoms of an acute coronary syndrome, mainly chest pain, less often dyspnoea, nausea or abdominal pain. An electrocardiogram is in keeping with myocardial infarction with (STEMI, 57–85% of cases) or without (NSTEMI, 15–43% of cases) ST elevation [2, 200, 201]. P-SCAD may cause cardiogenic shock or cardiac arrest. Compared to non-pregnant women with SCAD, the left main stem coronary artery dissection, dissection of the proximal coronary artery segments and multivessel involvement are more common coronary angiography findings in pregnant women. Conventional risk factors for myocardial infarction are only seen in about 1/3 of patients [201].

7.9.4. Diagnosis

The diagnosis of SCAD is made based on clinical presentation and coronary angiography findings. Five types of spontaneous coronary artery dissection have been identified based on angiographic findings: type 1 — with visible false lumen; type 2A — with visible long segmental stenosis and a normal artery segment distally to the stenosis; type 2B — with visible extensive stenosis, which reaches the distal tip; type 3 — with stenosis mimicking atherosclerosis; and type 4 — with distal coronary artery closure. In some cases, intravascular ultrasound (IVUS) or optical coherent tomography of coronary arteries are additionally needed to confirm the diagnosis of SCAD [197, 198].

7.9.5. Treatment

The diagnostic management of chest pain in pregnant women is similar to that in non-pregnant women and is shown in Figure 7.2A. The management of myocardial infarction in pregnant women is no different from that in other patients with myocardial infarction. According to the 2018 ESC Guidelines, primary percutaneous coronary intervention (PCI) is recommended as the preferred reperfusion therapy in pregnant women with STEMI (class of recommendation I, level of evidence C) or high-risk NSTEMI (class of recommendation IIa, level of evidence C). In stable, low-risk NSTEMI, a non-invasive approach should be considered (class of recommendation IIa, level of evidence C) [2]. However, given the predominant non-atherosclerotic aetiology of acute coronary syndromes (P-SCAD), the optimum management strategy for patients with P-SCAD needs to be discussed separately. It is currently believed that non-invasive treatment is the most appropriate approach in clinically stable patients with a patent true lumen or a short-segment obstruction. In clinically unstable patients with long-term myocardial ischaemia, invasive treatment should be considered. The percutaneous coronary intervention (PCI) with stenting is the method of choice which effectively restores normal coronary blood flow in about half of cases [200, 203]. The coronary

</tr>
</thead>
<tbody>
<tr>
<td>In order to quickly stop an episode of SVT, the manoeuvre stimulating the vagus nerve is recommended, followed by intravenous administration of adenosine</td>
</tr>
<tr>
<td>An intravenous administration of a selective β-1-blocker should be considered to immediately stop an episode of SVT</td>
</tr>
<tr>
<td>Ibutilide or flecainide* may be considered in order to stop AFL or AF in haemodynamically stable patients without organic heart disease</td>
</tr>
<tr>
<td>In each case of paroxysmal supraventricular tachycardia in haemodynamically unstable patients or those with accessory pathway-mediated AF, immediate cardioversion to sinus rhythm is recommended</td>
</tr>
</tbody>
</table>

*Cardioversion in patients with AF or AFL should generally be preceded by antithrombotic treatment
**B** Prevention of SVT and AF in pregnant women based on the ESC 2018 guidelines

- Long-term management of supraventricular arrhythmia in pregnant women
  - Selective beta-1-blockers or verapamil* are recommended in SVT prevention in patients without ventricular pre-excitation in ECG
  - Selective beta-blockers are recommended to control ventricular rhythm in patients with AT and AF
  - Flecainide**, propafenone** or sotalol*** should be considered in patients with SVT, AT and AF, if AV nodal blocking drugs prove ineffective
  - With no response to beta-blockers, digoxin* or verapamil* should be considered to control ventricular rhythm in patients with AT and AF
  - Ablation guided by electroanatomical mapping in an experienced centre should be considered in women with poorly tolerated or refractory SVT

*AV nodal blocking drugs should not be used in patients with ventricular pre-excitation or atrial fibrillation (AF) with ventricular pre-excitation; **In patients with definitive AT, flecainide and propafenone should be used in combination with AV nodal blocking drugs. Rule out: organic heart disease, reduced EF and left bundle branch block (LBBB); ***Class III (according to the Vaughan-Williams classification) antiarrhythmic drugs should not be used in patients with long QT syndrome (LQTS)

**C** Management of ventricular tachycardia in pregnant women based on the ESC 2018 guidelines

- Immediate cardioversion to sinus rhythm is indicated in each patient with VT, whether haemodynamically stable or unstable
- In order to terminate sustained, monomorphic VT in a haemodynamically stable patient, a beta-blocker, sotalol**, flecainide*, procainamide or overdrive stimulation should be considered

*Rule out: organic heart disease, reduced EF and left bundle branch block (LBBB); **Class III (according to the Vaughan-Williams classification) antiarrhythmic drugs should not be used in patients with long QT syndrome (LQTS)

**D** Prevention of idiopathic VT in pregnant women based on the ESC 2018 guidelines

- Long-term management of ventricular arrhythmia in pregnant women
  - Sotalol**, flecainide* or beta-blockers or verapamil* should be considered to prevent persistent idiopathic ventricular tachycardia if other treatments prove ineffective
  - Beta-blockers or verapamil are recommended in the prevention of idiopathic VT with haemodynamic compromise
  - Ablation guided by electroanatomical mapping in an experienced centre may be considered in women with poorly tolerated or refractory VT if other methods prove ineffective
  - ICD (preferably single chamber ICD) implantation, if clinically indicated, is recommended prior to conception. If ICD implantation in a pregnant woman, especially after 8 gestational weeks, is clinically necessitated, an echocardiography-guided procedure is recommended
  - Beta-blockers are recommended in women with congenital long QT syndrome (LQTS) and catecholaminergic polymorphic ventricular tachycardia (CPVT) in pregnancy and postpartum

*Rule out: organic heart disease, reduced EF and left bundle branch block (LBBB); **Class III (according to the Vaughan-Williams classification) antiarrhythmic drugs should not be used in patients with long QT syndrome (LQTS)

Figure 7.1B–D. Management of arrhythmia in pregnancy
artery bypass grafting (CABG) is an alternative treatment option, which should be considered in patients with the left main stem coronary artery dissection (as long as not proceeding with immediate PCI is a viable option taken their clinical presentation) and multiple vessel involvement, as well as those after ineffective or complicated PCI. In patients with cardiogenic shock, the left ventricular assistant device (LVAD), the extracorporeal membrane oxygenation (ECMO) or intra-aortic balloon pump (IABP) should be considered alongside reperfusion therapy. In exceptional cases, a heart transplant may be necessary [201]. Should surgical treatment or assist devices be necessary, delivery timing should be determined by a multidisciplinary team consisting of consultant gynaecologist-obstetrician, consultant anaesthesiologist, consultant perinatologist, and consultant cardiac surgeon.

Patients after P-SCAD should be started on dual antiplatelet therapy after stenting, and in those with postpartum left ventricular dysfunction, standard pharmacological treatment (beta-blockers, angiotensin converting enzyme inhibitors, mineralocorticoid receptor antagonists) should be used. Breastfeeding is not recommended in mothers on dual antiplatelet therapy (class of recommendation III, level of evidence C). The management of P-SCAD is presented in Figure 7.2B.

7.9.6. Prognosis
In the studies published to date, the hospital mortality rate was 0–4%, and the mean left ventricular ejection fraction was about 50%. Although long-term prognosis is favourable, there is a 10–20% risk of subsequent SCAD [200, 201]. Therefore, regular cardiac follow up is needed in those patients.

7.10. Peripartum cardiomyopathy
Peripartum cardiomyopathy (PPCM) is idiopathic cardiomyopathy presenting with HF secondary to left ventricular (LV) systolic dysfunction towards the end of pregnancy or in the months following delivery. The diagnosis can only be confirmed in the absence of a pre-existent cardiovascular disease as a key pre-requisite. PPCM is diagnosed with a left ventricular ejection fraction (EF) reduced to below 45%. The left ventricle may not be dilated. The risk factors for PPCM include HT, diabetes, smoking and such gestational risk factors as maternal age, parity, use of beta-blockers for tocolysis or malnutrition [204].

The pathophysiology of PPCM has not been fully explained. Recently, the signal transducer and activator of transcription 3 (STAT-3) have been postulated to play a role...
in PPCM. Another putative underlying mechanism involves oxidative stress, which appears to trigger induction of cathepsin D in cardiomyocytes, which subsequently causes increased cleavage of prolactin into an antiangiogenic and proapoptotic 16-kDa isoform. The 16-kDa prolactin has been shown to inhibit endothelial cell proliferation and migration, induce endothelial apoptosis and disrupt already formed capillary structures [205].
The diagnosis of PPCM is based on ruling out other causes of symptomatic HF. Most frequent initial presentation is NYHA class III or IV symptoms. The majority of patients present with symptoms in the first 4 months after delivery (78%), and only 9% present in the last month of pregnancy. Early diagnosis is the key determinant of prognosis. The ECG, serum B-natriuretic peptide (BNP) or N-terminal pro-BNP (NT-BNP) and echocardiography are recommended in women with dyspnoea, who present with congested lung fields, peripheral oedema and jugular venous distention [204]. Magnetic resonance imaging (MRI) should be considered. Although there are no PPCM-specific MRI findings, it enables ruling out acute myocarditis and myocardial ischemic injury [206]. A biopsy is not recommended as routine management (Fig. 7.3) [207].

Haemodynamically stable patients should be treated according to the recommendations for treatment of chronic and acute heart failure developed by the Heart Failure Association of the European Society of Cardiology Working Group on peripartum cardiomyopathy [2, 206, 208]. Treatment choices will depend on the clinical presentation and the timing of onset (before or after delivery). Before delivery, β-blockers (preferred β1-selective), vasodilators (preferably dihydralazine which is not available in Poland), nitrates and possibly (sparingly) diuretics are recommended. Vaginal delivery is preferred in stable patients.

After delivery, ACEI/ARB and β-blockers in maximum tolerated doses are recommended. Furthermore, mineralocorticoids (eplerenone) are recommended in women with EF < 40%. With a persistently low EF despite standard treatment for HF, a conversion from ACEI/ARB to sacubitril/valsartan is recommended. Ivabradine should be considered in patients presenting with persistent tachycardia despite β-blocker treatment.

Causal treatment may be considered after delivery. Bromocriptine dose of 2.5 mg twice a day for 14 days followed

---

**Figure 7.3.** Diagnostic algorithm for peripartum cardiomyopathy (PPCM)
by 2.5 mg once a day for 42 days is recommended. Additionally, anticoagulant treatment with heparin is recommended in patients with EF ≤ 35% or those treated with bromocriptine [2, 206]. In haemodynamically unstable patients (SBP < 90 mm Hg, O₂ saturation < 90%, lactates > 2 mmol/L), treatment with levosimendan (0.1 μg/kg/minute for 24 h) or mechanical circulatory support (MCS) devices such as intra-aortic balloon pump (IABP) or transcutaneous temporary ventricular support device (e.g. Impella) with or without ECMO [206] is recommended. Caesarean section is the preferred delivery method in unstable patients with PPCM [209]. In patients with persistently low EF < 35% despite optimal medical therapy, wearable cardioverter-defibrillator (WCD), implantable cardioverter-defibrillator (ICD), and possibly listing for heart transplantation should be considered.

8. MANAGEMENT OF POSTNATAL HYPERTENSION

Blood pressure generally decreases immediately after delivery both in women normotensive and hypertensive during pregnancy and may later increase to a peak at 3–6 days postpartum. A transient BP elevation may also occur in women after normal pregnancy and is associated with pain, medications, excessive fluid supply, water and sodium shift to the intravascular space or changes in the vascular tone which returns to its pre-gestational values. Having in mind the physiology of postnatal BP changes, antihypertensive treatment should be continued with a tight BP control during the first week postpartum, in order to avoid unnecessary or too aggressive antihypertensive treatment [210]. Figure 8.1 shows the postpartum management algorithm in women with HT during pregnancy.

Breastfeeding should not be discouraged in women with HT, including those on medical treatment. Although most antihypertensive drugs pass to human breast milk, their concentrations are usually much lower than in serum.

Methyldopa passes to human breast milk in small amounts. However, what limits its use in breastfeeding women is that it may trigger or exacerbate postpartum depression, sedation, and orthostatic hypotonia, which is why some guidelines recommend a conversion from methyldopa to another antihypertensive drug after delivery [210]. Beta-blockers pass to human breast milk in small amounts, although there are significant differences between the individual agents in this drug class. Metoprolol and labetalol are approved for use in breastfeeding women [9, 211, 212]. Newer β-blockers (nebivolol) and newer drugs with the mechanism of action identical to the one of labetalol (carvedilol) cannot be currently recommended in breastfeeding women due to lack of data.

Extended-release nifedipine is allowed in breastfeeding women with HT [9, 17], as it is passed to human breast milk in small amounts and no adverse effects have been reported in children breastfed by nifedipine-treated mothers [19, 213]. There is no data on the safety of amiodipine in breastfeeding women. Some guidelines allow it [210], however amiodipine seems a reasonable choice if extended-release nifedipine is unavailable. The data on the safety of verapamil in breastfeeding women is contradictory.

Angiotensin-converting enzyme inhibitors are contraindicated in pregnancy, but as they pass to human breast milk in negligible amounts, some of them are approved for the treatment of breastfeeding women by the American Academy of Pediatrics [214] as well as recommended by British [215] and French experts [9], subject to their contraindications. ACEI or sartans. Diuretics should not be used in breastfeeding women as they suppress lactation. The detailed information on the safety of medications in breastfeeding women (including their concentration in breast milk and infantile blood, as well as possible and reported adverse effects) can be found in the LactMed database - https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm, published by the US National Library of Medicine National Institute of Health and updated on an ongoing basis.

9. MANAGEMENT OF WOMEN WITH A HISTORY OF GESTATIONAL HYPERTENSION, PRE-ECLAMPSIA AND OTHER GESTATIONAL COMPLICATIONS

9.1. Long-term cardiovascular risk in women with history of gestational hypertension and pre-eclampsia

In recent years, there has been a growing interest in the relationship between gestational HT and PE (jointly referred to as pregnancy-induced hypertensive disorders) and cardiovascular complications and HT later in life. It has been noted that pregnancy-related hypertensive disorders and cardiovascular diseases share common risk factors, such as age, obesity, glucose metabolism disorders, kidney disease, as well as inflammatory and genetic factors [216]. Furthermore, women with gestational HT or PE had higher body mass index, higher BP values and pre-existent abnormal lipid profile pre-conception as compared to women without gestational HT or PE [217].
9.1.1. The risk of hypertension in women with a history of gestational hypertension and pre-eclampsia

It was shown that women with a history of pregnancy-induced hypertensive disorder had a higher risk of HT than in women with no history of pregnancy-induced HT or PE. An analysis of the Nurses’ Health Study II showed that women with a history of pregnancy-induced HT or PE have a higher risk of HT in 25–32-year follow-up. The risk was the highest in the first 5 years after delivery [218].

It should be emphasized that the association between PE and pregnancy-induced HT and subsequent HT can be seen as early as in the first months following delivery. The BP fails to normalise post-partum in some women. The study in women with a history of PE demonstrated HT in 24% of women, white coat HT in 18% of women and masked HT in 9.5% of women assessed with 24-hour BP monitoring at 6–12 weeks following delivery [219]. It also demonstrated that older age, earlier onset and longer

duration of gestational HT were associated with persistent BP elevation postpartum in women with a history of gestational HT [220].

9.1.2. Gestational hypertension and pre-eclampsia and the severity of cardiovascular risk factors

It was shown that the history of the pregnancy-induced hypertensive disorder is associated with significantly higher severity of modifiable cardiovascular risk factors. The Nord Trøndelag Health Study (HUNT) showed that women with a history of pregnancy-induced HT or PE in their first pregnancy had a higher pre-conception body mass index, waist circumference, blood pressure, heart rate, as well as glucose and triglyceride levels as compared to women without the history of pregnancy-induced HT or PE in their first pregnancy. After the first pregnancy, there was a parallel development in cardiovascular risk factor levels, but women with a normotensive first pregnancy had a time lag of 10 years compared with the PE group [221].

The Prevention of Renal and Vascular End-Stage Disease (PREVEND) study showed that women with a history of pregnancy-induced HT or PE more often had HT (a significant difference from the age of 35–40 years), diabetes mellitus (a significant difference from the age of 50 years) and lipid disorders (a significant difference from the age of 40 years) as compared to women without pregnancy-induced HT [222]. This indicates the need to monitor blood pressure, and lipid and carbohydrate metabolism disorder in women with a history of pregnancy-induced HT from middle age onwards.

9.1.3. Gestational hypertension and pre-eclampsia and the risk of cardiovascular events

It was also shown that women with a history of pregnancy-induced HT or PE have a higher risk of cardiovascular diseases and cardiovascular events than women without a history of pregnancy-induced HT.

The coronary artery calcium scoring with multi-slice computed tomography indicated that the frequency of coronary artery calcium score ≥ 95th percentile determined for the general population aged 45–55 years was 17% higher in women with a history of PE than in the general population. Atherosclerotic plaques were found in 47% of women and significant coronary artery stenosis was found in 4% of women. These results may indicate the accelerated progression of coronary artery atherosclerosis in women with a history of PE [223]. Women with a history of PE, HELLP syndrome and placental abruption were significantly younger (54 vs. 64 years old) upon the onset of stroke as compared to those stroke survivors without the history of PE [224]. Furthermore, a large Norwegian study demonstrated an increased risk of cardiovascular death in women with a history of pre-eclampsia in the first pregnancy [225]. The observational study from Northern California (median follow up of 37 years) also showed that the history of PE was associated with a higher risk of cardiovascular death as compared to women without a history of PE. This risk was particularly high in women with the onset of PE before 34 gestational weeks [226]. The association between PE and cardiovascular

| It is recommended to assess the severity of cardiovascular risk factors as well as the effect of their management (non-pharmacological and pharmacological) and a potential need to upscale it in women with a history of pregnancy-induced HT or PE at 3 months and one year following delivery and then once every year | Level B |
| Assessment for secondary HT should be considered in women with a history of gestational HT or PE, whose blood pressure has not normalised postpartum | Level C |
| Both office and out-of-office blood pressure measurements are recommended in women with a history of pregnancy-induced HT or PE | Level C |
risk was also confirmed in two large meta-analyses. The risk of PE remained significant even after adjustment for conventional cardiovascular risk factors [227, 228].

9.1.4. Other gestational complications and cardiovascular risk

Research shows a higher risk of HT and cardiovascular diseases in women with a history of gestational and perinatal complications, such as prematurity, low birth weight, stillbirth. These complications should be ascertained as a part of taking history to determine cardiovascular risk factor in women [229].

9.1.5. Long-term management of women with a history of gestational hypertension or pre-eclampsia

The studies discussed above indicate a significant association between pregnancy-induced hypertension and/or PE, and cardiovascular risk in later life [230]. Regular monitoring of cardiovascular risk factors, including regular blood pressure measurements, should be advised in women with a history of pregnancy-induced HT or PE. Lifestyle modification needs to be particularly emphasized [231]. Importantly, the presented data indicates that women with a history of pregnancy-induced HT or PE should be screened for cardiovascular diseases relatively short after the delivery, as the incidence of HT, diabetes and lipid disorder as well as a risk of cardiovascular events and cardiovascular death increase significantly from middle age (40–60 years) onwards. The management of women with a history of pregnancy-induced HT or PE has been outlined in Table 9.1.

10. IMPACT OF GESTATIONAL HYPERTENSION AND/OR PRE-ECLAMPSIA ON CHILDREN’S LONG-TERM HEALTH

Gestational HT and/or PE are among the main risk factors for prematurity and intrauterine growth restriction. Both prematurity and intrauterine growth restriction are associated with low birth weight, being significant risk factors for cardiovascular disease, metabolic syndrome and type 2 diabetes mellitus in adult life. Prematurity is a significant independent risk factor for chronic kidney disease (CKD). As a result of reduced nephron mass (total nephron number), CKD additionally predisposes an individual to develop HT, while HT is the main risk factor for the progress to end-stage CKD.

Estimates indicate that HT was diagnosed in 7.3% of prematurely born children at the age of 3, whereas the expected prevalence of HT at this age is 1–2%. HT was diagnosed in 6 to 25% of preterm children assessed at the age of 6–12 years, and in 16% of teenagers assessed at the age of 13–18 years, whereas the estimated prevalence of HT in the general population of 18-year-olds is about 10%. The risk of HT increases with age and is particularly high in children born before 33 gestational weeks. Population studies show a higher risk of HT in both appropriate for gestational age (AGA) and small for gestational age (SGA)
prematurely born children, with a higher risk found in boys than in girls [232–234].

A systematic review and meta-analysis of studies assessing the association between preterm birth (< 37 weeks), very low birth weight (< 1500 g) and SBP in later life are noteworthy. Blood pressure was measured in children, adolescents and adults born preterm. The controls were age-matched individuals born full-term. The meta-analysis included 10 studies (1342 individuals born preterm or with very low birth weight and 1758 individuals born full-term). The mean age on assessment was 17.8 years (6.3–22.4 years). Individuals born prematurely or with very low birth weight had SBP higher by about 2.5 mm Hg than that born full-term. The difference was even higher (3.8 mm Hg) in 5 selected studies. The authors conclude that children born prematurely or with a very low birth weight have moderately higher blood pressure and may have a higher risk of HT later in life. In the era of dynamic progress in neonatology, the view that prevention of HT should be extended to include individuals born prematurely or with very low birth weight is rightful and proper [235].

There was a negative correlation between the gestational age at birth and birth weight, and the risk of CKD. At the age of 7–8 years the prevalence of glomerular hyperfiltration assessed as microalbuminuria ranged between 8% and 12% in prematurely born children as compared to 0–2.1% in the age-matched general population. It is estimated that the risk of CKD in children born < 32 gestational weeks without additional complications is 1.7-fold higher than in the general population. Due to impaired renal compensatory mechanisms associated with reduced nephron mass (see below), the risk of CKD increases significantly in preterm neonates with acute kidney injury (AKI). CKD was found in this group in 10% of children within 1–3 years following neonatal AKI [236].

10.1. Pathogenesis of hypertension associated with prematurity and low birth weight
Multiple interrelated factors contribute to the pathogenesis of HT in prematurely born individuals, both AGA and SGA. Four main disorders were identified, which involve mechanisms leading to blood pressure elevation. These include [236]:
• impaired nephrogenesis and reduced nephron number;
• micro-damage of the central nervous system and sympathetic nervous system upregulation;
• the consequences of perinatal metabolic programming, including late metabolic effects of intrauterine growth restriction, postnatal pharmacological and nutritional treatment with associated body composition abnormalities and metabolic syndrome, as well as early vascular ageing (EVA) resulting in increased arterial stiffness, reduced the production of vasodilators by arterial endothelium and reduced placental micro-circulation.

10.1.1. Reduced nephron mass
The main cause of reduced nephron mass is impaired nephrogenesis, which physiologically lasts until the end of the 36th gestational week. Preterm birth is associated with a reduced nephron endowment (reduced nephron mass). A lower number of nephrons impairs renal ability to compensate for additional injurious agents (toxins, drugs, infections, metabolic factors) leading to AKI. Regardless of the above, preterm birth is associated with an increased risk of neonatal AKI, due to the additional morbidity associated with prematurity. Additionally, both AGA and SGA preterm children present with metabolic disorders of varying severity due to foetal metabolic programming under intrauterine stress. These factors additionally affect kidney function in later years and usually manifest clinically in prepuberty. The first abnormality associated with reduced nephron endowment is glomerular hyperfiltration, which is the key contributor to CKD progression and HT. Alongside glomerular hyperfiltration, a reduced nephron endowment (evaluated clinically in ultrasound as kidney volume or kidney length) is associated with salt sensitivity in preterm children. It is particularly pronounced in SGA children and can be observed as early as in 10-year-olds.

10.1.2. Sympathetic nervous system upregulation in children born prematurely and with low birth weight
The mean BP elevation, as well as decreased BP amplitude and heart rate, were demonstrated during 24-hour BP monitoring in preterm neonates [232].

10.1.3. Metabolic programming
Preterm infants, and especially SGA, are exposed to increased cortisol levels, which is one of the main factors causing metabolic programming, i.e. a shift to accumulating energy in visceral fat. According to the metabolic programming concept, if high-calorie nutrition is available, children with low birth weight, especially SGA, preferentially partition excess energy from food in visceral adipose tissue. This is accompanied by a relative reduction in muscle mass. As a result, they are uniquely susceptible to metabolic disorder manifesting as insulin resistance, elevated triglyceride levels, the tendency for hyperuricemia, and elevated blood pressure. In this context, it is important to achieve adequate body weight with hypercaloric diet quickly in premature and/or SGA neonates.

10.1.4. Early vascular aging
Preterm children, both AGA and SGA, have a smaller calibre of retinal arteries at the age of 6. The differences were the most significant in SGA children, who demonstrated the fastest weight gain in the first 24 months of life. Accelerat-
ed senescence of cord blood endothelial progenitor cells of premature neonates was also observed. Prematurely born individuals (both AGA and SGA) had increased arterial stiffness and higher BP. However, their presence was significantly modified by additional risk factors such as obesity and metabolic disorder.

10.2. Recommendations for early diagnosis of hypertension in preterm and/or small for gestational age neonates

Recommendations for post-discharge care in preterm neonates, both AGA and SGA, aimed at early diagnosis of HT are expert recommendations and represent class of recommendation I, level of evidence C. In Poland, this issue was discussed in the 2018 Recommendations of the Paediatric Section of the Polish Society of Hypertension and as a chapter in the ‘Standards of outpatient care for preterm neonates’ and recommended by the Polish Neonatal Society and the Polish Paediatric Society [237].

10.2.1. Screening for hypertension in the post-discharge care of preterm neonates (born < 33 gestational weeks)

Children with HT diagnosed prior to discharge from the neonatal ward should be consulted and provided with specialist care in a paediatric hypertension centre. Further diagnostic and therapeutic management should be based on the current paediatric recommendations of the Polish Society of Hypertension (2018) and the European Society of Hypertension (2016) [238, 239].

Children with concomitant renal and urinary tract pathology should remain under the care of a highly specialist paediatric nephrology, hypertension and urology centre. This will enable early treatment planning to address both urinary tract abnormalities and the need for renoprotective treatment.

Children presenting as normotensive prior to discharge from the neonatal ward should have blood pressure measured at every medical appointment. Automated BP measurement on the right arm is recommended as the basic method in children up to 3 years of age. Elevated BP found on automated measurement should be confirmed with the auscultatory method [239–241]. A referral to a paediatric hypertension centre is indicated in children presenting with HT. Due to the complex pathogenesis of HT in prematurely born children and concomitant neuroimmune abnormalities (see Chapter 10.1), a referral to a university paediatric centre with hypertension department/unit is recommended in such cases.

10.2.2. Definition of hypertension in newborns and infants

As the first weeks of life are associated with significant blood pressure changes additionally depending on the gestational age, the BP standards developed for neonates born between 26 and 44 gestational weeks should be used for the diagnosis of HT in newborns (Tab. 10.1). In older

infants and children up to 3 years of age, the standards outlined in The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents of the National High Blood Pressure Education Program (NHBPEP) Working Group on Children and Adolescent should be used. In children above 36 months of age, the applicable standards will depend on the measurement technique. As an automated BP measurement is most frequently used and recommended for screening, the norms developed in the OLA and OLAF studies should be used [239, 242].

Elevated BP found on the measurement with an automated oscillometric device should be confirmed with the auscultatory method. Just as in older children, the diagnosis of HT is based on the finding of BP above the 95th percentile determined for age in three measurements.

The classification of BP in prematurely born children is the same as in the general population and should be consistent with the recommendations of the Polish Society of Hypertension.
