The influence of hepatitis B virus (HBV) or hepatitis C virus (HCV) infections on the pregnancy course

Julita Nikolajuk-Stasiuk, Tadeusz W. Lapinski

Department of Infectious Diseases and Hepatology, Medical University of Bialystok, Poland

ABSTRACT

Objectives: The incidence of HBV infections among the pregnant in Europe falls within the range of 1–7%, whereas it is 1.7–4.3% for HCV.

The aim was to assess the course of pregnancy among women infected with HBV or HCV, and the condition of neonates in the fifth minute after the birth.

Material and methods: The study included 157 pregnant individuals infected with HBV, 53 infected with HCV, and 330 healthy pregnant women. None of the women infected with HBV and HCV as well as from the control group were infected with HIV, and none of them took intoxicants.

Results: Weight of neonates delivered by healthy women was higher as compared with children born by women infected with HBV or HCV (3.517 vs 3.347 and 3.366). The Apgar score of neonates delivered by women with HBV and HCV infections was lower as compared with the children born by healthy women (9.4 vs 9.3 vs 9.7, p < 0.05). Premature births occurred more often in HBV and HCV-infected women than in the control group (14.6% and 24.5% vs 6.96%; p < 0.05). Miscarriages were significantly more common among the patients with HCV infections as compared with the patients who were healthy (9.4% vs 1.8%; p < 0.05). In comparison with the healthy individuals, this group of patients experienced pruritus (10.5% vs 4.2%; p < 0.05), oedemas (9.4% vs 2.4%; p < 0.05), and hypertension (9.4% vs 1.5%; p < 0.05) more often. An increase in HBV loads was observed between the 6th and 28th–32nd week of pregnancy among the infected with HBV, and then, a decrease was observed in the 6th months after the delivery.

Conclusions: The women infected with HBV without HBsAg (–) and the infected with HCV are subject to common incidence of premature births. Women infected with HCV often experience oedemas, hypertension, and pruritus.

Key words: HBV or HCV infection in pregnancy; childbirth

INTRODUCTION

The incidence of hepatitis B virus (HBV) infections in the pregnant women throughout Europe ranges from 1% to 7% [1]. Pregnant women are usually aware of the HBV infections; less often they learn about the infection upon examination performed during initial stages of the pregnancy. Neonates delivered by women infected with HBV become infected in less than 1% of cases in Europe [2]. The likelihood of a neonate becoming infected in a perinatal or postnatal way does not exceed 10% due to widely applied active and passive prophylaxis of children delivered by HBV-infected women [a vaccine and a hepatitis B immunoglobulin (HBIG) specific serum administered within 12 hours after the delivery] [3, 4]. It is possible for a child to become infected via an intrauterine way. Also, a child may become infected by an HBV-infected woman who has high HBV viraemia (> 200,000 IU/mL) or high surface antigen of the hepatitis B virus (HBsAg) concentration (> 4–4.5 Log10 IU/mL) [3]. The risk of such an infection regards most often the women with HBV viraemia above 6 Log10 IU/mL and hepatitis B envelope antygen (HBeAg) (+) presence. The likelihood of an infection with the virus increases proportionally to the viraemia increase [4, 5]. The devised guidelines present the ways of dealing with women infected with HBV that want to become pregnant (Tab. 1).

Antiviral drugs used in the pregnant infected with HBV decrease the risk of infecting the foetus, however, none of the currently used nucleoside/nucleotide analogues (NAS) are listed as category A according to Food and Drug Administration (FDA), and thus, their use in pregnant women should be done cautiously. European [European Association for the Study of the Liver (EASL)] and American [American Association for the Study of Liver Diseases (AASLD)] guidelines allow for administering Tenofovir Disoproxil Fumarate (TDF) between the 24th and 32nd week of pregnancy.
The aim of the work was to perform a clinical assessment of the pregnancy course among women infected with HBV or HCV. The following was determined: type of delivery, neonates’ condition in the fifth minute after the delivery, weight at birth, and sex. All patients had their biological parameters of liver function monitored. The patients infected with HBV had viraemia monitored throughout the course of pregnancy and after the delivery. HCV-infected patients had the virus genotype and initial viraemia assessed.

MATERIAL AND METHODS

The study included 157 pregnant women infected with HBV aged from 21 to 42 (mean age: 29 y/o), and 53 pregnant women infected with HCV aged from 19 to 46 (mean age: 28 y/o). Three hundred and thirty healthy pregnant women aged from 18 to 40 (mean age: 28 y/o), who lived in the same region as the infected women, constituted a control group.

None of the women infected with HBV and HCV as well as from the control group was HIV-infected and none of them took intoxicants.

Qualification criteria for HBV-infected women included no HBeAg and exclusion of cirrhosis. None of the women infected with HBV had been qualified for the treatment earlier nor had been treated with antiviral drugs. The following was monitored among the HBV-infected women: viraemia, ALT activity, serum ALP within the first six weeks of pregnancy, between the 28th and 32nd week of pregnancy and six months after the delivery. In the group of the pregnant infected with HCV, viraemia and virus genotype were determined in the fifth week of pregnancy, whereas ALP and ALT activity was determined in the first six weeks of pregnancy, between 28th and 32nd week of pregnancy, and six months after the delivery.

Neonates had their clinical condition assessed in the fifth month of life by means of Apgar score.

All patients had serum HBsAg, HBeAg, anti-HBe, and anti-HCV antibodies assessed once by means of MEIA (microparticle enzyme immunoassay) and using Abbott tests (Germany).

HBV-DNA quantity was determined by RT-PCR using sets of COBAS AmpliPre/COBAS TagMan HBV Test, version 2.0 produced by ROCHE. The sensitivity amounted to 9 IU/mL, whereas linearity was 20 IU/mL.

Among women with positive anti-HCV, quantitative assessment and genotype were determined by RT-PCR method and using sets of COBAS HCV Test, version 2.0 produced by ROCHE (Germany).

The patients provided their informed consent to participate in the study according to the protocol accepted by the Bioethical Committee of Medical University in Białystok (R-I-002/134/2019).

Statistical analysis of data was conducted by using STATISTICA.PL produced by StatSoft for Windows 10 operating system. The study used Mann-Whitney U test, Spearman's rho, student's t-test, and chi-squared test ($\chi^2$). The level of significance was set at $p < 0.05$.

HBsAG — surface antigen of the hepatitis B virus; HBeAg — hepatitis B envelope antigen; TDF — Tenofovir Disoproxil Fumarate; HBV — hepatitis B virus; ETV — Entecavir; NA — Nucleoside/Nucleotide Analogues
RESULTS

Mean pregnancy duration in HBV- and HCV-infected as well as among the healthy patients was similar and amounted to 38–39 weeks. The frequency of spontaneous labour was comparable and amounted to 52% for HBV patients, 42% for HCV patients, and 58% in the control group.

Weight of children delivered by healthy women was higher as compared with children delivered by HBV- or HCV-infected females (3.517 vs 3.347 vs 3.366). In case of HBV-infected women, the weight was significantly lower as compared with the healthy women (Fig. 1).

Having assessed the Apgar score at the fifth minute of life, neonates of HBV- and HCV-infected women showed lower scores as compared with children born to healthy females (9.4 vs. 9.3 vs 9.7; p < 0.05), (Fig. 2).

Premature births occurred significantly more often in the HBV- and HCV-infected as compared with the control group (6.96% vs 14.6% and 24.5%; p < 0.05). In the group of HCV patients, miscarriages were significantly more common as compared with the healthy patients (9.4% vs 1.8%; p < 0.05). Among the HBV-patients, miscarriages were more frequent than in the control group, however, it was not statistically significant (Tab. 2).

Nausea was the most observed adverse reaction in all the pregnant women. HCV-patients significantly more often experienced pruritus (10.5% vs 4.2%; p < 0.05), oedemas (9.4% vs 2.4%; p < 0.05), and arterial hypertension (9.4% vs 1.5%; p < 0.05) as compared with the healthy patients (Tab. 3).

Among the HBV-patients, an increase in viraemia between the 6th and 28th–32nd week of pregnancy was confirmed in 46% of patients, a decrease in 15% of patients, and in 39% of cases there were no changes. In 90% of patients without detectable viraemia, in the sixth week of pregnancy, its increase was not confirmed between the 28th and 32nd week of pregnancy.

Among the HBV-patients, an increase in viraemia was observed between the 6th and 28th–32nd week of pregnancy.

1,2 — statistically significant difference; HBV — hepatitis B virus; HCV — hepatitis C virus.
The highest increase was confirmed among the pregnant with initial viraemia of HBV DNA ≤ 4 Log10 IU/mL in the 6th week of pregnancy.

In four HBV-patients, who experienced a miscarriage, HBV viraemia was at 4 Log10 IU/mL, whereas in two it was undetectable.

HCV infections werecased in 67% of patients by 1b genotype, in 20% — 3a, and in 13% — 4 genotype.

An influence of HCV RNA viraemia on possible clinical symptoms in the pregnant females was not observed.

In HBV- and HCV-patients, a mean ALT and ALP activity during the pregnancy did not change and remained within normal limits.

There were no cases of infecting a neonate both regarding HBV and HCV.

**DISCUSSION**

Patients with chronic HBV infections in Europe and the US are usually characterized by the lack of HBeAg. The situation is different in Asia, and it may exert a significant influence on the course of this infection among the pregnant.

HBV and HCV infections influence an increased activity of proinflammatory cytokines: IL-2, IL-6, IL-10, macrophage migration inhibitory factor (MIF), and TNF-α. In pregnant women they may cause an increase in the percentage of miscarriages, premature births, and a worse clinical condition of delivered neonates that is determined by the Apgar score [10]. Cui et al. [5] compared 513 pregnant women that suffered from chronic HBV infections with 20,491 pregnant women without this infection and showed a statistically more frequent occurrence of miscarriages in HBV patients that were pregnant. In the authors' studies, premature births were observed more often in HBV- and HCV patients. However, the frequency of miscarriages was statistically higher among HCV patients as compared with the healthy individuals.

Although miscarriages were often observed in HBV patients, there was no statistically significant difference as compared with the healthy females.

During pregnancy, high concentration of adrenal corticosteroids may influence the increase in HBV viraemia [11, 12]. In most pregnant women with HBV infections and absent HBeAg, viraemia is stable. However, in some patients an increase in HBV-DNA and ALT activity is observed during late pregnancy and in the postnatal period [13]. In the authors' studies, an increase in viraemia was observed at the turn of the 2nd and 3rd trimester, and then, a decrease was observed during the 6th month after the delivery. A significant increase with 2 Log10 was observed among the patients with HBV-DNA ≤ 4 Log10 IU/mL in the 6th week of pregnancy. In other pregnant females, a worrying increase in viraemia was not confirmed. Occasionally, during the perinatal period a significant HBV reactivation, and serious liver damage with encephalopathy and hepatic coma may occur [14]. Among such patients, an occurrence of disseminated intravascular coagulation (DIC), hepaticorenal syndrome, brain oedema, and bile duct infections were observed. Interestingly, prophylactic administration of NA from the 2nd/3rd pregnancy trimester does not decrease the risk of liver failure, although it prevents a child from becoming infected [15]. Miscarriages were observed in six pregnant women infected with HBV. However, in none of them an HBV-DNA viraemia was confirmed to exceed 3 Log10 IU/mL.

Having assessed the incidence of adverse events, a more common occurrence of oedemas, hypertension and pruri-
