ABSTRACT

Objectives: Abnormal vaginal flora (AVF) is a result of excessive growth of some aerobic bacteria and fungi in relation to the scarce presence of Lactobacillus spp. It has been suggested that AVF is responsible for preterm birth and such neonatal conditions as infections or sepsis.

The aim of the study was to assess the influence of excessive vaginal colonization with aerobic bacteria and fungi on the selected postnatal parameters of newborns, duration of pregnancy and length of hospitalisation of neonates.

Material and methods: Retrospective data of all 1057 patients who delivered between 01.2019 and 06.2019 in the Department of Perinatology of Medical University of Lodz was analyzed. Eight hundred nine patients were included in this retrospective study. The study group consisted of 396 patients with abundant growth of aerobic bacteria and fungi obtained between 26 and 42 weeks of gestation, while 413 patients with physiologic vaginal biocenosis constituted the control group. Two hundred forty-eight patients (23.46%) were excluded from the study due to incomplete data.

Results: Patients with abnormal vaginal flora (AVF) gave birth prematurely (9.09%) more often than patients with balanced microflora (5.31%), p = 0.038. Newborns of mothers with AVF obtained an Apgar score under four more frequently (1.21% vs 0%; p = 0.024). Eutrophic neonates were born less frequently in the study group (82.08% vs 88.65%; p = 0.025). Hospitalisation period was longer for children of mothers with AVF (mean of 6.30 ± 9.87 days) than those of mothers from the control group (mean of 5.06 ± 5.30), p = 0.025. Newborns of mothers with AVF developed perinatal infections more often (23.97% vs 15.94%; p = 0.004). Four infants died in the study group whereas no deaths were recorded in the control group (p = 0.045). The most prevalent pathogens were: Streptococcus agalactiae (GBS) 57.32%, Candida spp. 39.64%, Klebsiella spp. 9.85%, Staphylococcus aureus 7.32%. Signs of infection were more frequently recorded in newborns of mothers infected with Klebsiella spp. (35.90% vs 19.16%; p = 0.011). Premature birth was more prevalent in GBS carriers (11.81% vs 6.28%; p = 0.022).

Conclusions: Abundant growth of aerobic bacteria in the 3rd trimester of gestation contributes to preterm birth, causes the development of infection signs in newborns, increases their mortality rate and prolongs hospitalisation period.

Key words: vaginal microflora; aerobic vaginitis; PROM

INTRODUCTION

The quantitative and qualitative composition of microorganisms in the vagina changes during a woman’s life and depends on many factors such as, age, alterations in hormone levels (during the menstrual cycle, pregnancy, menopause), sexual intercourse and hygiene habits [1–3].

Due to the many improvements in modern microbiological diagnostics and findings of the Human Microbiome Project — a research initiative conducted by the National Institute of Health, our knowledge of the vaginal microflora has significantly increased [4]. Vaginal microbiota is dominated by Lactobacillus spp. (L. crispatus, L. iners, L. jensenii and L. gasseri).
[5]. Lactobacillus species are responsible for the acidic pH of the vagina due to the production of lactic acid from glycogen stored in epithelial cells [2]. These symbiotic bacteria cover vaginal mucosa, preventing the adhesion and penetration of pathogens. Moreover, they produce hydrogen peroxide, bacteriocins and bacteriocin — like substances, which strengthen the mechanisms against invasion and colonization by opportunistic pathogens [1].

The pregnancy period is characterized by the exceptional stability of the vaginal microflora [5–7]. This balance is due to the increased estrogen levels, which provide an abundance of glycogen in epithelial cells, resulting in the proliferation of Lactobacilli [1, 5].

The most common anomalies associated with microbial imbalance in the vagina are bacterial vaginosis (BV), aerobic vaginitis (AV) and candidiasis. Bacterial vaginosis is a condition characterized by a rapid increase in the anaerobic bacteria population, at the expense of Lactobacilli. In this case, Prevotella, Mobiluncus, Gardnerella vaginalis, Ureaplasma and Mycoplasma are detected in vaginal smears. Traditionally we use Amsel’s criteria in clinical settings [8, 9] however, Gram staining is the diagnostic standard [10]. Numerous studies confirm the impact of BV on the frequent occurrence of preterm premature rupture of membranes (PPROM), preterm birth (PTB) delivery before 37 completed weeks of gestation) and low birth weight (LBW) birth weight of less than 2500) [1, 11, 12].

Vaginal dysbiosis can also manifest as aerobic vaginitis (AV). In this case, reduction of the population of Lactobacilli and multiplying aerobic bacteria leads to inflammation [1]. The most common bacteria associated with AV and clinical features are presented in Table 1 [1, 13–15]. AV is associated with adverse obstetric outcomes including PPROM and PTB [16, 17]. Maternal colonization with GBS in pregnant women during delivery could be associated with neonatal pneumonia, meningitis and even severe sepsis [18, 19]. Candidiasis is a fungal infection caused by any type of Candida. Pregnancy increases the frequency of vaginal Candida colonization, which is favored by high glycogen concentration, resulting from the influence of hormones [20]. The number of studies assessing the relationship between candidiasis and obstetric complications is not sufficient, and the results of many studies are inconclusive [21]. The most convincing analyses confirm the relationship between candidiasis (even asymptomatic colonization) and higher incidence rate of PTB and LBW [22–24].

Considering that the aforementioned pathologies are often asymptomatic, oligosymptomatic or symptoms may imitate physiological changes during pregnancy, and the fact that they have a significant impact on specific obstetric complications, it is important to actively screen for vaginal microflora disorders in pregnant women. Considering the importance of the balance in vaginal microflora during pregnancy we decided to perform a retrospective study to assess the influence of vaginal colonization with pathogenic bacteria and fungi on the adverse perinatal outcomes in mothers and newborns.

**Objectives**

The aim of the study was to assess the influence of excessive vaginal colonization with aerobic bacteria and fungi on the selected parameters of newborns, duration of pregnancy and length of hospitalisation of neonates.

MATERIAL AND METHODS

Out of 1057 patients who gave birth in the Pirogow Clinical Hospital in Lodz between January and June 2019, there were 809 patients included in this retrospective study. Those patients had their vaginal flora sampled upon hospital admission for delivery. In the given timeline patients gave birth between 26 and 42 weeks of gestation. Swabs were taken from the posterior vaginal wall. Next, smears and bacterial staining were performed, followed by microscopic evaluation. The microscopic evaluation consisted of assessing the Lactobacillus count, presence of other bacteria and fungi and leukocyte count. Based on the results, patients were divided into two groups. Patients whose smears did not reveal any abnormalities in bacterial or fungal growth and had high Lactobacillus count constituted the control group — 413 patients. The study group consisted of 396 patients whose smears revealed abnormalities (low Lactobacillus count, abundant growth of other bacteria and fungi), which will be referred to in the article as abnormal vaginal flora (AVF). The abnormal result was considered an indication to obtain bacterial or fungal cultures. Depending on the species, microorganisms were cultivated between 18–96 hours. The isolated bacteria and fungi were assessed for antimicrobial drug sensitivity using a disk diffusion test. The results were uploaded to an online database. All the patients in the study group and the control group were also tested for GBS presence through rectal and vaginal swabbing. Patients who were not tested for GBS, regardless of their flora composition were excluded from the study as well as patients tested for GBS but not tested for other abundant bacterial or fungal growth — 248 patients (23.46%).

Baseline characteristics and past medical and obstetric history of subjects — age, parity, gravity as well as data concerning the pregnancy in question: way of delivery (C-section/natural birth/forceps or vacuum), gestational age during delivery and the occurrence of PROM were taken. In addition, characteristics of neonates born to mothers enrolled in the study were obtained in order to assess neonatal well-being and post-delivery condition. The characteristics were: neonatal birth weight, Apgar score after the 1st, 3rd, 5th and 10th minute after birth, signs of infection in the neonates, signs of respiratory distress, hypotonia, positive bacterial blood culture and the length of post-delivery hospitalisation of the neonates. The following criteria were used as to indicate signs of infection in neonates based on Chan et al. [25], elevated C-reactive protein (CRP) — over 10mg/L and white blood count (WBC) — over 30 000/µL, fever, positive bacterial or fungal blood culture. Respiratory distress was defined using the criteria by Liu et al. and Sochocka et al.: labored breathing (retractions of intercostal muscles, nasal flaring), crackles on auscultation, pulmonary oedema, the necessity to use mechanical ventilatory support, typical X-ray chest findings (diffuse alveolar opacification), metabolic and mixed acidosis or hypoxia/hypercapnia in blood tests [26, 27].

Microsoft Excel 365 (Microsoft, Redmond, Washington, United States of America) and STATISTICA 13.3. (TIBCO Software, Palo Alto, California, United States of America) software were used for statistical analysis. Descriptive data was presented as numbers, percentages, and means with standard deviations. The statistical significance of the association between events was determined with the use of Chi² Pearson test. In addition, due to the large study group and the assumed normal distribution of variables, statistical differences in numerical variables were determined using parametric tests, namely the student’s T test. P-values were represented to three decimal numbers and 0.05 was used as a cutoff for significance.

RESULTS

Out of the 1057 patients delivered in our hospital between January 2019 and June 2019, a total of 827 underwent vaginal discharge sampling upon hospital admission for delivery (between 26 and 42 weeks of gestation). AVF was observed in the case of 396 patients while 413 had physiological composition of vaginal flora (abundance of Lactobacillus spp., scarce or no other bacterial species, absence of no leukocytes and fungi).

The maternal characteristics are presented in Table 2. There was no significant difference in maternal age, gravity and parity between groups. There was however, statistically significant difference in gestational age between both groups (38.63 vs 38.95 gestational weeks).

Delivery data analysis is presented in Table 3. Premature birth (26 + 0–36 + 6 weeks of gestation) occurred significantly more often in the study group (9.09% vs 5.31%; p = 0.038).

Neonatal assessment also included birth weight analysis which is presented in Table 4. Hypotrophy was more prevalent in the study group (10.17% vs 7.08%), but the difference was not statistically significant (p = 0.104). On the other hand, eutrophy was observed less often in the study group (82.08% vs 88.65%; p = 0.025). Hypertrophy occurred more often in the study group; however, the difference was insignificant (7.75% vs 4.35%; p = 0.057).

Figure 1 represents the prevalence of infection signs among neonates. As shown on the graph, infants born to mothers from the study group developed infections statistically more often than infants born to mothers from the control group (23.97% vs 15.94%; p = 0.004).

There was no significant difference in the development of respiratory distress or hypotonia among infants of both groups.

Regarding perinatal mortality, it was significantly more frequent in the study group — four children of mothers with AVF died, while no deaths were recorded in the control group (p = 0.045). Due to severe post-delivery conditions, two children of mothers from the study group were admitted to the Intensive Care Unit, whereas there was no such necessity for children of mothers from the control group.

Among children of patients with abnormal microflora the average length of hospital stay was 6.30 (± 9.87) days while for children of patients whose microflora did not show any abnormalities, the length was calculated as 5.06 (± 5.30), (p = 0.025).

As for microbiological results, 15 bacteria and fungi species were cultivated from the smears and are presented in Table 5. The most common abundant pathogen growth cultivated from the samples was GBS — 57.32%, followed by Candida spp. — 39.64% and Klebsiella spp. — 9.85%, two or more pathogens were cultivated from the samples of 104 patients (26.26%).

In the aim of assessing whether any specific type of microbial growth affected neonatal well-being we analyzed such parameters as: signs of infection in newborns, preterm

delivery rate, respiratory distress and reduced Apgar score and calculated correlations between the above mentioned and the prevalence of certain species in the genital tract. Our results are presented in Table 6, 7 and 8.

Signs of infection in newborns: elevated CRP — over 10 mg/L and WBC — over 30 000/µL, fever, positive bacterial or fungal blood culture [25].

The influence of specific bacterial and fungal strains on the occurrence of preterm birth is presented in Table 7. The results showed that the incidence of preterm birth (26 + 0–36 + 6 weeks) was higher among patients infected with GBS than those not infected (p = 0.022).

The results shown in Table 8. indicate that the presence of Klebsiella spp. in the genital tract is associated with a higher incidence of postnatal respiratory distress in newborns (p = 0.036).

There was no relationship between an Apgar score below 8 and presence of specific bacteria or fungi cultures in the mother’s genital tract.
DISCUSSION

The balance in the vaginal microflora is essential for maintaining a healthy vaginal environment and preventing colonization with opportunistic pathogens. Insufficient Lactobacilli growth enables bacteria and fungi to thrive and grow abundantly which may cause signs of infection in pregnant females, result in perinatal complications and have consequences on the well-being of their newborns [16, 28]. AV is a newly established condition characterized by the imbalance in the microflora accompanied by an increased inflammatory reaction and followed by a consequential immune response [28]. In addition, the imbalances in the microflora facilitate the invasion and growth of fungi such as Candida [15].

Our results showed that patients with abnormal bacterial or fungal growth delivered prematurely more often than those not infected. However, our study included patients who gave birth between 26 and 42 weeks of gestation as this was the specificity of patients admitted to the department in the given timeline. Thus, we only proved a connection between AVF and preterm birth between 26 + 0 and 36 + 6 weeks of gestation. According to literature [29], GBS is significantly associated with preterm birth which was also confirmed in our study. Interestingly, there was no statistical correlation between PTB and Klebsiella spp., S. aureus or Candida spp. infection. It is well known that the occurrence of PTB is a result of multiple factors, but they were not considered in this study as our prime focus was the influence of vaginal flora.

Many studies confirm that abnormal vaginal flora is associated with deterioration of newborn’s condition and need for intensive care for neonates [28]. In our study we confirmed that it is also connected to reduced Apgar score. Abnormal vaginal flora may contribute to the development of signs of infection in the newborns [30]. In our study infants born to mothers with disturbed balance in vaginal microbiota developed infections statistically more often than infants born to mothers without abnormalities.

Special attention should be paid to abundant growth of Klebsiella spp. Many sources indicate that Klebsiella spp. has a considerable impact on the occurrence of neonatal infections. According to Omwandho et al. [31], this strain of bacteria accounted for over 50% of bacterial infections among neonates and was responsible for 70% of neonatal deaths. Our study recorded a higher incidence of neonatal infections among newborns of mothers infected or colonized with Klebsiella as well as a connection between the infection with this pathogen and signs of respiratory distress in newborns.

Due to the recognized impact of GBS on the pregnancy outcomes, screening for GBS is recommended during the last trimester of pregnancy, generally between 35 and 37 weeks of gestation [32]. In addition, antibiotic prophylaxis should be administered to GBS colonized women perinatally [32]. Although there is evidence of the harmful impact of Klebsiella on neonatal well-being, there are no similar recommendations and procedures for patients infected with this bacterium [33]. The prevalence of abnormalities in vaginal microbiota correlated with longer post-delivery hospitalisation. Prolonged hospitalisation of infants, especially those born in bad condition generates higher costs [34]. Regarding the prevention of AV and associated bacterial and fungal colonization, Nv Geneg et al., emphasize that consistent condom uses and college-level education is a protective factor for AV. Unmarried status, menarche at 13–15 years, Intrauterine device (IUD) use, long-term use of antibiotics, use of panty liners and frequent vaginal douching are listed as risk factors [35].

Our study has some limitations. First, the retrospective nature of the study did not allow us to assess the clinical symptoms of vaginitis in patients. Secondly, we were not able to assess the immunological and biochemical characteristics of patients’ vaginal discharge which is why the diagnosis of AV could be argued. Our study was conducted in a gynecologic hospital in a big city which does not reflect the general Polish population. Multicenter studies are therefore needed for comparison. As strengths of our study, we consider the big number of patients in the study group — all patients hospitalized after their 30th week of pregnancy in our department in the chosen timeline were included in the analysis.

CONCLUSIONS

We proved a connection between abundant growth of aerobic bacteria in the 3rd trimester of gestation and preterm birth, the development of infection signs in newborns, an increase in their mortality and extension of hospitalisation period. Preventive measures such as screening tests should be carried out regularly and efficient follow-up should be implemented. Those measures should be taken into consideration particularly in the case of Klebsiella spp. growth as it was proven to contribute to the development of signs of infection and respiratory distress in newborns.
