ABSTRACT

Background: Microbiological monitoring of surfaces used for food preparation, as required by the Hazard Analysis and Critical Control Points (HACCP) plan, is important in risky conditions as those observed in the kitchens of ships. Limits to introduce a classification of risk levels and methods to adopt in conditions as those occurring in tankers have not been investigated. This paper presents the results of the “Healthy Ship” project on HACCP monitoring of surfaces used in food preparation on Italian flag tankers.

Materials and methods: Microbiological monitoring was carried out on 19 tankers between 2013 and 2017. Food handlers were also trained on board ship according to HACCP standards. Contact plates (ISO 18593:2004 compliant) were used to determine the colonies and bacterial charge according to the Wirtanen and Salo’s method.

Results: A total of 1074 samples, 108 before the first course, 168 after the first course, 390 during the period of refresher (2015–2016), and 408 after the refresher training, were obtained from the three main kitchen surfaces: the worktop, cutting board, and kitchen sink. A good level of hygiene was observed in 56.9% of all samples, 0.1% were classified as adequate, and the remaining 43% as poor. The highest contamination was observed on the cutting board and kitchen sink and involved the total aerobic count. The only surface with inadequate levels of hygiene was the worktop. A reduction of contaminated samples was noted after training.

Conclusions: Our results suggest that continuous training should be provided for personnel responsible for handling foodstuffs on board ships.

Key words: microbiological surveillance, food-handling, seafarers, HACCP, food hygiene, food safety

INTRODUCTION

Food contamination can be attributed to natural contamination from raw materials (primary contamination) or to cross-contamination caused by the transfer of microorganisms from contaminated surfaces or vehicles (such as water, air, etc.) onto food. Appropriate standards of hygiene in the environment where food is prepared, such as surfaces, types of equipment and utensils are essential to prevent microbial contamination and to obtain safer food [1]. In the last decade, this topic has stimulated research to develop surfaces with antimicrobial activity [2–4].

This problem is more relevant in conditions characterised by a higher level of risk such as kitchens on board ships, and, in particular, the kitchens of cargo ships. Merchant (cargo) ships do not carry health professionals, may be involved in long journeys and seafarers work in an enclosed environment. Despite the low number of crew-members working and living on a cargo ship, seafarers are exposed to quite a high risk of infection [5–13]. To minimise the risk of infection and food poisoning in a closed environment such as the one found on a cargo-ship, ensuring microbiological safety in the kitchen should be a priority.

Taking into account that gastrointestinal disorders are at the first or second place as problems affecting seafarers healthy, the Centro Internazionale Radio Medico (CIRM) has...
launched a project called “Healthy Ship”. This project includes a series of preventive measures aimed at protecting seafarers’ health as a survey on the knowledge of seafarers about food hygiene, and a panel of interventions to improve the quality and the control of food and water distributed on board [13–18]. CIRM is the Italian Telemedicinal Maritime Assistance Service (TMAS) and represents the Centre with the largest worldwide experience [10, 12, 19]. This project included periodic training of galley’s personnel and periodic on board inspections.

The present work reports the results of microbiological monitoring on the kitchen surfaces of cargo merchant ships before and after the seafarers training and suggests a new procedure for storing samples. Analysis started on August 2013 and was concluded in October 2017.

**MATERIALS AND METHODS**

**MICROBIOLOGICAL MONITORING**

Analysis of the microbiological safety of kitchens and of the compliance with good production practices was performed by a direct on board inspections done between August 2013 and October 2017, on tankers belonging to two shipping companies. Monitoring was carried out twice a year (frequency of 6/7 months) by medical and technical CIRM personnel on 19 ships, when they were docked. Ships were tankers shuttling service from not more than 6 years from the date of enrolment in the project. They were sailing from 7 to 10 days. Origin and destination were in the Mediterranean and in the Black sea. The “Healthy Ship” project established a training course on Hygiene and Sanitation for Ship’s Messman and Stewards on the main ships first officers, properly trained by the Hygiene group of the School of Pharmacy of Camerino University. Training included periodic training of galley’s personnel and periodic on board inspections.

Monitoring on the kitchen surfaces of cargo merchant ships before and after the seafarers training and suggests a new procedure for storing samples. Analysis started on August 2013 and was concluded in October 2017.

**METHOD VALIDATION**

Before monitoring kitchen surfaces on board, the sampling procedure, using contact plates, was repeated 6 times, in duplicate, in the Hygiene Laboratory of Camerino University, to verify its implementation. For each replication a plate was incubated immediately after the sampling. Other plates were incubated at 4°C after storage periods (24, 48, 72, 96 h), and then incubated to count the number of Colony Forming Units on 20 cm² (CFU/20 cm²). Total aerobic count, coliforms and fungal charge were tested independently. The data were transformed using Log10 and then over-dispersion and repeatability limits were calculated. Each test might be affected by casual errors caused by the way the samples were obtained, the temperature of incubation, the number of colonies, etc. The sum of these errors adds an additional dispersion of results, namely over-dispersion. This value is then added to the dispersion of the Poisson distribution. The
method could be considered valid if over-dispersion does not statistically modify the theoretical dispersion of Poisson data.

The statistical analysis was conducted using the formula:

\[ \chi^2_{n-1} = \frac{\sum_{i=1}^{n} (c_i - \bar{c})^2}{\bar{c}} \]

where \( n \) is equal to number of observations, \( c_i \) is the value given to each observation and \( \bar{c} \) is the mathematical average of observations.

The data distribution was evaluated in agreement with the theoretical Poisson distribution if: \( \chi^2 \) experimental \( \leq \chi^2_{n-1} \) theoretical (with \( n-1 \) degrees of freedom, \( p \geq 0.95 \)).

No significant differences were noticeable in the CFU/20 cm² results between plates incubated immediately after contact if stored at 4 °C. The method resulted was valid, and in particular: the test of aerobic bacteria count by a \( \chi^2 \) of 1.90 ≤ \( \chi^2 \) theoretical of 11.071 (\( n = 6; \ p \geq 0.95 \)), the test for coliforms (Escherichia coli) by a \( \chi^2 \) of 2.144 ≤ \( \chi^2 \) theoretical of 11.071 (\( n = 6; \ p \geq 0.95 \)). The test for Enterococci by a \( \chi^2 \) of 3.687 ≤ \( \chi^2 \) theoretical of 11.071 (\( n = 6; \ p \geq 0.95 \)) and the test for fungal by a \( \chi^2 \) of 0.05 ≤ \( \chi^2 \) theoretical of 11.071 (\( n = 6; \ p \geq 0.95 \)).

**HYGIENE CLASSIFICATION LEVEL**

Lacking an international classification, in this study, the hygiene level of the kitchen on board was categorized into classes of risk and consequently hygiene levels, applying the classification proposed by Wirtanen and Salo [17]. This method was based on three different scales and has three different levels of judgment for contact surfaces. The three scales in relation to the hazard level are loose, normal and strict. Levels are good (A), adequate (B) and poor (C).

The limits for coliforms (Escherichia coli), aerobic bacteria count (37 °C) and fungi, yeast and moulds are summarised in Table 1.

**STATISTICAL ANALYSIS**

The results obtained for each parameter (Enterococci, Escherichia coli, total aerobic bacteria count at 37 °C, and total fungal charge) monitored were processed using a descriptive statistical analysis, the Shapiro-Wilk test for non-normality, and the Paired Student’s t test using XLSTAT software [22]. In the Shapiro-Wilk test, if the data showed a p-value > \( \alpha \), the null hypothesis (H0) could be accepted, and therefore the distribution resulted as normal [23].

To analyse the efficacy of training, the results obtained from the monitoring process conducted in the first visit and after the refresher training were compared using the Paired Student’s t test. The variables on which the Paired Student’s t test was based are shown by the number of colonies found, both before and after the safety inspection was conducted, relative to aerobic bacteria count, coliforms, Enterococci and fungal load, and the p-values at 95% confidence interval were measured.

**RESULTS**

During the 4 years spent monitoring 19 ships, 1074 microbiological samples, 108 before the first course, 168 after the first course, 390 during the period of refresher (2015–2016), and 408 after the refresher training, from the three most critical surfaces (worktop, cutting board and kitchen sink) were collected and analysed.

When examining the percentage of positive samples over time, we noted a similar trend for all species monitored, and a decreasing of the positive samples percentage after the refresher training completed in 2016 (Fig. 1).

Among the total (1074) microbiological samples examined, a good level of hygiene was reported for the 56.9% of surfaces, 0.1% was classified as adequate and 43% as poor. In particular, after the first course, and before the refresher, the percentage of positive samples was 39.1%; while after the refresher the number of positive samples was reduced to a percentage of 28.6%.

This suggests that the development of the microbiological charge until 2016 is related with the lack of respect for good procedures by food handlers.

The results on surfaces classified as good, adequate and poor reported in percentage for each single surface are summarised in Figure 2.

Figure 2 shows that the “good level” is the level registered with the highest frequency for all microbiological parameter. An adequate level for aerobic bacteria counting was found only in a worktop sample, during the first inspection in 2013. In particular, the total aerobic count recorded

CFU/20 cm² — Colony Forming Units on 20 cm²
in this sample was 25 CFU/20 cm², inside the range of 15 and 50 CFU/20 cm², defined as an adequate level. Considering the surfaces classified as poor, the cutting board was recorded as the surface with the highest percentage of positive samples by fungal, *Escherichia coli*, and aerobic bacteria count. Whereas, the enterococci were recorded with the lowest percentage, but values were similar to the other microorganisms recorded.

In all tankers, a reduction in the frequency of positive samples was found. In fact, by evaluating the positivity or negativity of samples, a ratio of 0.5 (50%) between poor and good samples in all ships was detected. Only one ship showed a ratio equal to 0.8 (80%) among samples.

To test the effects of training, the average of the colony-forming units in the first sampling (year 2013) was compared with the average of colony-forming units detected in sampling after doing the refresher course (2017). As expected, the monitored surfaces in the first sample showed a CFUs concentration over the limits. In the second sample, the concentration of CFUs was within limits, with a higher than 99% reduction for all surfaces. Different levels of contamination were found among surfaces. The kitchen sink and the cutting-board had the highest contamination levels of total bacteria count at 37 °C. The worktop was contaminated too, but showed a lower concentration of microorganisms. When considering the microorganisms found in a higher frequency, the total bacterial count at 37 °C on all surfaces was the principal cause of microbial contamination (Fig. 3). The total fungal charge showed a similar trend on all surfaces while the Enterococci were found in a higher concentration on the worktop. The highest concentration of *Escherichia coli* was detected on the worktop and on the cutting board (Fig. 3).

Sanitary conditions were positive after seafarers employed in the kitchen underwent a period of training. In fact, after the first surveillance (2013) followed by a negative outcome, a food safety training was conducted and during the second inspection the efficacy of this training was evaluated. After the training was carried out, all surfaces showed a decrease in the level of microbial charge. This result was common for all microorganisms and for all surfaces (Fig. 3). Analysing the percentage of reduction of CFUs between the first surveillance and the surveillance after refresher, the highest percentage of reduction (100%) was noticeable for *Escherichia coli* and Enterococci in all surfaces monitored, whereas a reduction of 97.9% of the total aerobic charge was obtained for the worktop. The distribution resulted as normal and the Student’s t-test showed the efficacy of the food safety training especially in the reduction of total bacteria count, the principle cause of contamination (Table 2).

**Figure 1.** Percentage of positive samples in the years of monitoring
DISCUSSION

This paper has looked at the procedures applied to identify the level of microbial contamination over all surfaces in contact with food and, in particular, the efficacy of training given to food handlers on board tankers. In our work, surfaces used in food production on board cargo ships were categorised as strict and not normal or loose, because they are exposed to a high risk of contamination due to the hard conditions on cargo ships [17, 24–30]. In these surfaces, a microbiological survey was conducted to identify the ones which were more susceptible to the risk of contamination. Even if the number of samples increased over time, the decrease in the percentage of contaminated samples showed that the training program on safe food handling on good handling practices (GHP) (surfaces sanitation procedures), followed by continuous inspections on board, ensured surfaces were under control.

In terms of evaluation of the effects of monitoring surfaces initially classed under a “poor” level of hygiene reached an “adequate” level after the second visit. Analysis of the statistical significance value of the Student’s t test obtained in correlating the microbiological charge, in particular of total bacterial count (37 °C), between the first and second visit showed the positive effect on the hygienic quality of surfaces monitored and allowed the real value of intervention to be evaluated. This result is comparable with similar findings of other researchers that emphasized the importance of training food services staff on board ships [25].

Microbiological surveillance revealed a relevant percentage (43%) of surfaces classified as “poor”. Probably, the bacteria come from the manipulation of foods by food-handlers. In fact, after checking the compliance of the storage temperature of food boarded, and of the cooling room temperature, we have investigated the compliance of sanitisation procedures. As a result, we have found a cleaned cold room, while all the criticalities were observed in the kitchen where the ordinary manipulations of food take place. In particular, the greater contamination was related to total mesophilic aerobic counts. This charge is a standard parameter used to assess the microbiological quality of surfaces used by food-handlers. In particular, an increase of the total mesophilic charge could be caused by the presence of microorganisms transferred by food employees, particularly by using dirty hands.

The presence, on surfaces monitored, of some bacteria such as Enterococci and Gram-negative, such as coliforms (Escherichia coli), suggests strengthening the knowledge and procedures relating to the personal hygiene of food-han-
Figure 3. Microbiological charge detected in the first sampling before the first training course, year 2013 (before) and after doing a new refresher course, year 2017 (after); A. Kitchen sink sampled: n = 172 (36 before and 136 after); B. Cutting board sampled: n = 172 (36 before and 136 after); C. Work top sampled: n = 172 (36 before and 136 after); CFU — Colony Forming Units

Coliforms (Escherichia coli), associated with a high aerobic mesophilic bacteria count, revealed a lack in the sanitation procedures because aerobic heterotrophic bacteria are more capable of growing on surfaces enriched by food residuals. For instance, the high contamination recorded on the cutting board with the lack of respect for the GHPs can be explained. The presence of Enterococci, even if detected with a lower number of viable counts than Escherichia coli, has been a severe hazard of contamination for the seafarer’s health. In fact, Enterococci are common in the environment, and when present in food they can infect people, causing severe infections [34].
The sampling of fungi showed they were present in all surfaces monitored. This result suggests the environmental conditions of the kitchen should be further investigated, particularly levels of aeration and damp.

The training of seafarers on HACCP and the constant monitoring practices on board promoted a decrease of microbial positive samples. The ratio of 0.5 (50%) between positive and negative samples collected on cargo ships showed that microbiological surveillance achieved only half the objective. In this respect, we should mention that during the inspections, some unsafe practices such as the production of food in high quantities with consequent storage of leftovers were recorded. In fact, the production of surplus food was closely related to the risk of undercooked food and cross-contamination. Recent studies have shown that even at low temperatures, some bacteria such as Salmonella spp., are able to contaminate meat (poultry), highlighting the risks of consuming undercooked meat [35, 36].

A correct implementation of GHPs within a HACCP plan is the principal practical measure used to stop the spread of cross-contamination. In fact, cross-contamination events were attributed to deficient hygiene practices, contaminated equipment, contamination via food handlers, processing, or inadequate storage, generally a result of poor hygiene [37, 38]. The results of this study suggest checks on board merchant ships should be continued to improve sanitation standards operating procedures (SSOPs) and, finally, to enforce the knowledge of food handlers employed on board. In comparison to other studies [23, 39] that evaluated positive effects after training, in our case constant monitoring allowed critical hygienic conditions to be found.

CONCLUSIONS

Our study suggests that it is necessary to carry out a constant activity of training on food handlers over time to take under control the contamination episodes. The fact that merely introducing a HACCP plan is not sufficient to remove the mishandling of food, but continuous monitoring on board combined with refresher training for the seafarers must be adopted, is an important result of our study, as well as one of its strong points. In fact, only by applying this type of approach it will be possible to keep the hygiene level of kitchens on board ship under control. Furthermore, this research demonstrated the possibility of carrying out microbiological monitoring on board cargo ships docked far away, proposing restrictive limits to classify the hygiene levels of surfaces used for food preparation. However, one limit of this study was given by the restricted number of ships used in the study as well as the difficulty of carrying out continuous monitoring, as is normally done on land, on ships which are often at sea for long periods of time.

It is important to remember that seafarers represent one of the most isolated demographic working groups in the world, with limited access to medical care because they are at sea for days or weeks before ships can reach a port and also are exposed to high physical stress [40–42].
