A 63-year-old male, with no history of chronic conditions, was admitted to the Department of Cardiology due to myocardial infarction. The patient complained of chest discomfort. Physical examination revealed no significant abnormalities; heart rate was regular at 62/min, blood pressure 154/95 mm Hg. Electrocardiography showed anterior and inferior wall ischemia. Invasive coronary angiography and primary percutaneous coronary intervention of the left anterior descending artery were performed, followed by staged percutaneous coronary intervention of the circumflex artery on the next day. Laboratory test results showed elevated troponin T levels. Bedside echocardiography revealed segmental myocardial systolic dysfunction with reduced ejection fraction (Biplane Simpson’s method 35%), with no significant valvular disease. There was an longitudinal structure, within the left atrium (Figure 1A). Echocardiography was then repeated in the echocardiography laboratory, and showed the
presence of an additional structure located at the lateral wall of the left atrium, adjacent to the left atrial appendage (LAA) and left superior pulmonary vein. The motion of this structure was consistent with the cardiac cycle, and its echogenicity was comparable to that of heart tissues (Figure 1B and 1C). This finding prompted a tentative diagnosis of a prominent Coumadin ridge. A transesophageal echocardiography (TEE) showed a structure, which resembled a cotton swab, with a narrow proximal part and bulbous distal part (Figure 1D). Cardiac magnetic resonance imaging (cMRI) showed a structure in a four-chamber view, which was not visible in any other sequences and showed no contrast enhancement (Figure 1E). This structure was then assumed to be a prominent Coumadin ridge; therefore, no further investigations were performed nor was any anticoagulant treatment initiated.

A Coumadin ridge is an anatomic variant, which is an embryological remnant detected in the left atrium, between the left superior pulmonary vein and the LAA. Being aware of the existence of this structure may be crucial for the differential diagnosis of any focal lesions found in the left atrium and planning of percutaneous transcatheter interventions, such as ablation or LAA closure. The Coumadin ridge shows inter-individual variability, and its estimated prevalence is 60% on gross postmortem examinations [1]. The ridge tissue fold contains the ligament of Marshall, an autonomic nerve bundle, and a small atrial or sinoatrial-node artery. The vestigial ridge is usually invisible on echocardiography; however, if prominent, the structure may be misdiagnosed [2]. In TEE its shape resembles that of a cotton swab (“Q-tip sign”) [3]. Computed tomography or cMRI can be useful assessments for the differential diagnosis [4]. Utmost caution should be exercised every time a Coumadin ridge-like focal lesion in the left atrium is diagnosed, since myxomas, fibromas, and thrombi may be also found in the same location [5]. In TEE the Coumadin ridge interferes with good imaging of the LAA, which should be imaged omitting the structure, preferably “above” the entrance to the LAA, moving the structure to the side. Coumadin ridge may also impede the flow of blood in the LAA and may be associated with thromboembolic complications, which requires further study. Imaging study results should be interpreted in the clinical context, with the thromboembolic risk and possible cancer history taken into consideration. In the case presented here, TEE and cMRI were used to determine the nature of the lesion.

Being aware of the presence of anatomic variants within the left atrium, along with their structure and location, is indispensable to avoid initiating unnecessary therapeutic interventions and expanding the scope of diagnostic investigations.
