A 19-year-old male was admitted to the hospital with a two-month history of hemoptysis. Previously healthy, with no significant family history, he was initially examined for lung pathology. On admission, a chest X-ray showed disseminated consolidations in the lungs. Computed tomography showed subpleural opacities and multiple, bilateral solid nodules with ground-glass opacities (Figure 1A, 1B). The nodules were more dispersed in the peripheral lobules, which is suggestive of neoplastic spread [1].

The chest scans also showed an irregular mass in the right atrium. The patient was transferred to the cardiac surgery department. Transthoracic echocardiography (TTE) revealed a 70 × 45 mm heterogeneous lobulated tumor in the right atrium infiltrating the free wall of the right atrium, right ventricle, and tricuspid valve, suggestive of malignancy. Cardiac magnetic resonance demonstrated inhomogeneous late gadolinium enhancement of the mass infiltrating the pericardium (Figure 1C, 1D).

Laboratory tests showed elevated D-dimer concentration, liver enzymes, and fibrinogen. Cancer biomarkers were within reference ranges. The most probable diagnosis was a primary cardiac neoplasm with metastatic spread; pulmonary lesions were highly suggestive of metastases of angiosarcoma. Surgical resection was precluded due to the anatomical location and infiltration of the tumor. Biopsy of the lesion was necessary to implement any systemic treatment. Nevertheless, the patient refused this procedure and asked for discharge.

TTE confirmed enlargement of the tumor to 80 × 70 mm (Figure 1E, 1F). Due to hemoptysis the patient required numerous blood transfusions and intensified pain therapy. Biopsy of the tumor was eventually performed and poorly differentiated angiosarcoma cells classified as G3 were found. The patient was immediately transferred to the oncological center to undergo palliative chemotherapy. During transport, his condition got worse and he was admitted directly to the Intensive Care Unit with a suspicion of pulmonary embolism. After 2 days the patient died due to multiple organ dysfunction and septic shock.

Cardiac angiosarcomas are a rare pathology with an average survival period of 7 months if diagnosed in the metastatic stage [2]. Lesions of the right heart have a poorer prognosis compared to those on the left. They are described as infiltrative, bulky, heterogeneous lobulated masses with areas of hemorrhage and necrosis on echocardiography [3]. Surgical resection is essential, and both complete and partial resection contribute to longer survival. Adjuvant chemotherapy is used due to frequent metastases and their efficacy in reducing tumor tissue. Combining surgical resection, chemotherapy and radiotherapy can extend survival time up to 3 years [4].

If the tumor is not resectable, biopsy and histopathological analysis are crucial to implementing systemic treatment. This case exemplifies that if angiosarcoma is suspected, the biopsy must not be postponed. The course of the disease is very aggressive with extensive progression in tumor mass seen after two weeks. A prompt diagnostic workup is of vital importance for the rapid implementation of targeted therapy and requires the involvement of a multi-specialist team [4, 5].
