A 56-year-old patient (male, former smoker) was admitted to a municipal hospital due to gradually increasing fatigue, exercise dyspnea, and chest pain persisting for 3 weeks. The new diagnosis of heart failure with reduced ejection fraction (HFrEF) was established, the standard treatment was applied, and the resolution of symptoms was observed. After a few days, a routine test for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was positive. Seven days later, dyspnea and chest pain reappeared. The patient was transferred to the cardiology department dedicated to COVID-19 patients.

On admission to our department, a computer tomography with pulmonary angiogram revealed bilateral, multifocal, ground-glass opacities in the lungs and no signs of pulmonary embolism. Inflammatory markers and N-terminal pro-B-type natriuretic peptide levels were significantly increased, whereas the troponin level was in the normal range. The patient’s blood pressure was 86/60 mm Hg, and SpO₂ was reduced to 89%. The electrocardiogram showed inverted T waves in leads V1–V6 without ST-segment depression or elevation. The echocardiography revealed reduced ejection fraction (26%), severe hypokinesia of the anterior wall, and apical segments (without any features of myocardial necrosis). Viral pneumonia with HFrEF was diagnosed. Mild symptoms of low cardiac output were observed during the first several days of hospitalization. Recurrent episodes of chest pain were also observed over the next few days. Coronary angiography was performed as soon as the circulatory system was stabilized, and the infection was under control [1]. The coronary angiography revealed an occluded left anterior descending artery (LAD) in the proximal segment (Figure 1A). The distal part of the LAD could be seen due to the presence of the collateral circulation from the right coronary artery (Figure 1B) and the circumflex branch. No other significant occlusions of the coronary arteries were observed.

We decided to perform revascularization in this patient due to resistance HFrEF to pharmacotherapy, recurrent chest pain episodes, and likely short LAD occlusion time (about 6 weeks history of chest pain episodes and dyspnea). The heart team recommended percutaneous revascularization which was performed the next day. Right radial access and the antegrade technique were used. The amplatz left guide catheter 6F provided adequate support, the LAD occlusion was crossed by guidewire Pilot 50 (Figure 1C), balloon pre-dilatations were performed, and a new drug-eluting stent (3.5 × 40 mm) was implanted with a successful final result (Figure 1D). No recurrence of chest pain symptoms and reduction in the severity of heart failure symptoms were observed after this procedure. The patient was discharged as a COVID-19 convalescent.

The rapidly progressing global COVID-19 pandemic presents many difficulties for the functioning of health care systems [2, 3]. Data showed that in Poland the COVID-19 pandemic is associated with a large decline in the performance of invasive cardiology procedures in the setting of the coronary syndrome [4]. Our case report shows that the SARS-CoV-2 infection often coexists with other chronic diseases, which may also be exacerbated. SARS-CoV-2 infection
should not delay treatment of HFrEF and coronary artery disease if the general condition of the patient allows for the required procedures [1, 5].
