Breast cancer is the leading cause of cancer-related deaths in women worldwide. Patients with breast cancer are at an increased risk of cardiovascular toxicity, presently defined as cancer therapy-related cardiovascular toxicity (CTR-CVT). This article provides a summary of the current knowledge on pharmacological cardiovascular prevention in breast cancer patients. The ESC guidelines on cardio-oncology have defined CTR-CVT. Baseline risk stratification with widely accepted risk scores is essential to identify patients at higher risk of CTR-CVT. The guidelines recommend the use of angiotensin-converting enzyme inhibitors (ACE-I), angiotensin receptor blockers (ARBs), and beta-blockers as preventive medications in high-risk patients. Clinical trials have shown ambiguous results for ACE-I/ARBs and beta-blockers in reducing cardiotoxicity, while co-administration of ACE-I/ARBs and beta-blockers did not show additional benefits in preventing cardiac dysfunction. Further research is needed to verify the efficacy of novel cardioprotective medication and optimize pharmacological strategies for cardiovascular prevention in breast cancer patients.

Key words: cardio-toxicity, cardiovascular prevention

Introduction

Breast cancer is the most diagnosed cancer and the leading cause of deaths due to cancer among women worldwide. In the United States, it is the second most common cancer among female patients and is the second leading cause of cancer deaths with incidence being relatively stable over the past two decades [1, 2]. As well as in the US, in Europe, breast cancer is the most common cancer among female patients, with an estimated 522,000 new cases and 137,000 deaths in 2020 (3,4). It should be noted that both in Europe and in the USA, the mortality rates of breast cancer
have been declining likely due to advances in its successful detection and introduction of more efficacious therapeutic protocols.

Nonetheless, breast cancer patients are often at an increased risk of developing cardiovascular disease, due to a wide variety of factors, including baseline disease, cancer treatment strategies, as well as lifestyle changes associated with cancer [5, 6]. In the recent years, attempts have been made to stratify the risk of development of cardiovascular disease, especially a rather acutely developing cardiac dysfunction, labelled as “cancer therapy-related cardiovascular toxicity (CTR-CVT)” [7]. In patients at risk of CTR-CVT development, the introduction of preventive methods prior to cancer treatment might reduce the risk of the development of such condition. Among those, pharmacological strategies can play a critical role in reducing this risk of cardio-toxicity, with possible influence on patient’s quality of life, efficacy of cancer treatment, and long-term outcomes. The aim of the manuscript is to briefly summarize the current knowledge on the pharmacological cardiovascular prevention in patients with breast cancer.

**Definition and clinical significance of cancer treatment-related cardiovascular toxicity**

The definition of cardiotoxicity, or as it should be named at present CTR-CVT, has been established in the recent ESC guidelines on cardio-oncology [7]. The guidelines have divided the broad spectrum of CTR-CVT on the basis of the pathomechanism and clinical manifestation, including the development of heart failure (HF), or myocarditis, toxicity to the vascular structures, or the presence of hypertension, or rhythm disorders. Most notable is the definition of cancer therapy-related cardiac dysfunction (CTRCD), which encompasses the wide spectrum of myocardial damage associated with anticancer therapy. The definition of CTRCD according to the ESC guidelines is presented in table I. It should be noted that the definition allows to diagnose CTRCD solely on the basis of echocardiography, even in the absence of any clinical signs or symptoms of HF, although the guidelines recommend other imaging modalities, including magnetic resonance imaging in certain clinical situations [8]. The other important definitions, including the specific criteria for diagnosing myocarditis, defining vascular complications and arterial hypertension or arrhythmias were also thoroughly defined in the guidelines. The unification of those definitions is crucial, since it will allow to more cautiously monitor their real prevalence, as in the past the frequencies reported in the literature could have varied significantly due to differences in diagnostic criteria for each condition [9].

As patients with other types of cancer, patients with breast cancer who receive treatment are at risk of developing CTRCD, which can lead to serious complications and may significantly impact
the quality of life. The most prevalent types of cardiovascular adverse effects are presented in table II. Moreover, cardiac failure can interfere with assumed cancer treatment protocol, and result in a necessity to either reduce the dosing or the frequency of administered therapies, thus affecting the effectiveness of the cancer treatment, and affecting outcomes [10–12]. Finally, it has been demonstrated that the development of CTRCD is associated with an increased long-term risk of HF in patients who experienced CTRCD [13, 14].

The years of experience with treatment of patients with cancer have demonstrated how to - at the present stage of knowledge – stratify patients according to their baseline risk for development of CTRCD. As a rule of thumb, an early identification of patients at higher risk of medical procedures has been widely proven to improve prognosis and is therefore recommended. Similarly, the ESC guidelines on cardio-oncology specify that it’s best to define the baseline risk right at the time of cancer diagnosis, even before initiation and planning of treatment. Although there is no single, established pathway on how to optimally screen and then risk-stratify patients according to their baseline CV risk, the parameters which according to the ESC should be taken into consideration before initiation of anti-cancer treatment are listed in table III, while the detailed guidelines on cardiovascular prevention in patients with cancer are presented in table IV.

After thorough assessment of patients’ baseline cardiovascular risk, the physicians should stratify the patient’s therapeutic toxicity risk. In the recent years, multiple risk scores for identification of CV toxicity were analysed, although the detailed Heart Failure Association–International Cardio-Oncology Society (HFA-ICOS) provides the most comprehensive data and thus has been included in the recent ESC guidelines as the preferred one, with a class IIa recommendation [15–17]. The HFA-ICOS classification is based on almost every factor assessed at baseline and defines the risk with regard to the strategy of anti-cancer treatment, depending on the possible influence of every individual drug group on every risk factor. For instance, the very high risk of cardiotoxicity in patients with cardiac amyloidosis has been highly documented only for multiple myeloma therapies. With regard to chemotherapy schemes utilized in the treatment of breast cancer, being most often anthracyclines and/or anti-HER2 drugs, the risk of CTR-CVT is very high only if the patients have had HF or CTR-CVT in the past, or if the patient scheduled for trastuzumab had received trastuzumab before. With regard to other chemotherapeutic groups used in the treatment of breast cancer, such as VEGF inhibitors, there are plenty of factors associated with a very high risk of CTR-CVT, including any history of HF or even asymptomatic left ventricular contractile dysfunction, as well as the history of any significant atherosclerotic
cardiovascular disease. Any other factors of known significance, including the history of MI/PCI, decreased LVEF or advanced age should be noted and based on their calculable association with CTR-CVT, the total risk score could be then evaluated and then divided into low-, moderate- or high-risk.

The stratification of CV toxicity risk at baseline is important, because on the basis of the initial assessment, all further surveillance should be performed. Those could include routine follow-up visits in the oncology clinic if the patient is in the low-risk of CTR-CVT, or a more detailed follow-up if the patient is in the moderate risk group. However, the general rule should be that patients with low- and moderate risk of CTR-CVT should not have the anti-cancer therapy delayed and should initiate treatment at the earliest possible stage. In those categories, a referral to cardiology clinic or at least to an experienced cardiologist is necessary only if the CTR-CVT develops, with an exception that a treating oncologist might consider referral to the cardiology department regardless of the development of CTR-CVT in patients at moderate risk.

If the patient is considered as of a high- or very-high risk of CTR-CVT, after baseline assessment, a referral to cardiooncology clinic is mandatory, and the cardioprotective medication should be considered at baseline to mitigate that risk during cancer treatment. Moreover, in those patients, the guidelines recommend to discuss all the risks and benefits associated with potentially cardiotoxic treatment in a multidisciplinary team to establish the most optimal further strategy.

Cardiovascular prevention

In the general population, the present ESC guidelines on cardiovascular prevention specify non-pharmacological, and pharmacological interventions which should be initiated to reduce the cardiovascular risk [18]. However, many of the suggested preventive strategies were deemed ineffective in patients with cancer. Although a straightforward answer to such discrepancy in outcomes is difficult to be presented, it could be speculated that among patients with cancer, it is the baseline disease, and often the presence of various CV risk factors, that increase the CV risk already at baseline and thus reduce the reckoned efficacy of preventive strategies.

The ESC guidelines on cardiooncology recommend initiation of „cardio-preventive“ medication in patients with high- or very-high risk of CTR-CVT, stratified according to the initial baseline risk assessment. In those patients, an anti-cancer drug with least possible cardiotoxicity risk should be selected. Moreover, the guidelines recommend consideration of administration of specific cardioprotective drugs in those patients. Those, apart from implementation of strategies
mitigating the risk of anthracycline-induced cardiotoxicity, including treatment with dexrazoxane or liposomal anthracyclines, refer to introduction of neurohormonal therapies, including angiotensin-converting enzyme inhibitors (ACE-I) or angiotensin receptor blocker (ARBs), beta-blockers and preventive treatment with statins [19]. ACE-I/ARBs and beta-blockers are the groups of drugs commonly used as a first-line therapy in patients with heart failure, or hypertension, and have been shown to improve cardiovascular outcomes in patients with cancer as well [20].

**Angiotensin-converting enzyme inhibitors or angiotensin receptor blocker**

Two large, randomized trials – Prevention of cardiac dysfunction during adjuvant breast cancer therapy (PRADA) and Cardiotoxicity Prevention in Breast Cancer Patients Treated With Anthracyclines and/or Trastuzumab (SAFE) investigated the role of primary prevention of CTR-CVT with the use of ACE-I or ARBs specifically in patients with breast cancer. In PRADA, 130 patients with an early breast cancer, who were treated with anthracyclines underwent randomization to either candesartan (member of ARBs) or metoprolol (a beta-blocker). Prevention with candesartan but not with metoprolol was associated with a statistically significant reduction in LVEF decrease (candesartan vs. non-candesartan: 0.8% vs. 2.6%, p=0.026). In contrary, treatment with metoprolol was associated with smaller increases in levels of cardiac troponins [21]. However, in the long-term analysis, no differences in LVEF were observed in any of the studied groups [22].

In the SAFE trial, which has been performed in a 4-arm design, an interim analysis performed after 12 months of follow-up revealed that in patients with no prior cardiovascular disease, cardioprotective therapy with ramipril (an ACE-I) or bisoprolol (a beta-blocker), was associated with improved echocardiography outcomes than in patients treated with placebo [23]. In detail, patients treated preventively with both drugs demonstrated a slight (0.1%) improvement in left ventricular global longitudinal strain (GLS), while GLS was reduced in the placebo arm (by 6.0%) as well as in patients treated with ramipril or bisoprolol monotherapy (respectively by 1.5% and 0.6%, p < 0.001). Moreover, the number of patients experiencing a major reduction of LVEF (by ≥10% in the 3D-echocardiography) was lower in the group treated with ramipril and/or bisoprolol, with 6.8%, 11.5% and 11.4% of patients experiencing such endpoint when treated with respectively combined therapy, ramipril or bisoprolol monotherapy. In patients administered with placebo, 19% experienced a major LVEF reduction [23].

The molecular rationale for prevention of CTRCD with either ACE-I or ARB is broad, although it is speculated that it is mostly based on the preclinical studies, in which mice with knockout of angiotensin II type 1a receptor gene, are at a significantly reduced risk of anthracycline-induced
cardiotoxicity [24]. Moreover, in a general population, administration of ACE-I or ARBs was associated with improvements on both macroscopic and microscopic levels. Inhibition of RAA resulted in a reduction of myocardial fibrosis, while intracellularly, in improvement of mitochondrial function, reduction of oxidative stress, and positive alterations in the calcium homeostasis [25, 26], all of mechanisms which might explain benefits associated with ACE-I/ARBs in patients with cancer.

**Beta blockers**

The efficacy of beta-adrenolytics in the prevention of CTR-CVT has already been discussed in the two aforementioned trials, which evaluated metoprolol and bisoprolol, two of four beta-blockers recommended in the treatment of heart failure in overall population. The efficacy of the third of them, was evaluated in the Carvedilol for Prevention of Chemotherapy-Related Cardiotoxicity (CECCY) trial [27]. In this, placebo-controlled trial performed among 200 patients with HER2-negative breast cancer, chemotherapy and parallel treatment with carvedilol, a non-cardioselective beta-blocker did not reduce the occurrence of cardiotoxicity (defined as the proportion of patients with a ≥10% reduction in LVEF, carvedilol vs placebo: 14.5% vs. 13.5%; p = 0.99) and did not influence the LVEF assessed as a continuous variable at 6-month follow-up, when compared with placebo. However, the trial did provide results analogous to those from the PRADA trial, as the use of carvedilol was associated with a lower increase in cardiac troponin I during anthracycline treatment. Thus, it may be speculated that there might be a class-effect of beta-blockers in reducing the risk of myocardial injury associated with anthracycline treatment. Among the potential mechanisms of such cardioprotective activity, the anti-oxidative effect exhibited by beta-blockers has been proposed, what is demonstrated e.g. in a lower risk of intracellular lipid peroxidation and mitochondrial dysfunction [28].

In general, both ACE-I, ARBs and beta-adrenolytics have constituted the cornerstone of modern treatment of heart failure, as they significantly attenuate the pathophysiological neurohormonal pathways in patients with HF. In patients with a decreased cardiac contractile function, a pathological cascade based on the sustained activation of neurohormonal responses develops. The elements of the cascade include the hyperactivity of adrenergic system, and activation of the renin-angiotensin–aldosterone pathway. All aforementioned drug groups act as the inhibitors of those pathways, and by stabilizing the cardiac homeostasis they were proved to reduce morbidity and mortality in patients with chronic heart failure [29].
Finally, based solely on the data presented above, it could be speculated that if both preventive strategies (ACE-I/ARB and beta-blockers) were proved effective, their co-administration might further increase the efficacy of prevention of CTR-CVT. However, in the previously mentioned PRADA trial, one arm of patients has been randomized to parallel preventive strategy with candesartan and metoprolol, and, in comparison with monotherapy groups, no significant differences were observed with regard to LVEF reduction. On the other hand is the important OVERCOME trial, in which 90 patients with malignant hemopathies treated with intensive chemotherapy were randomized to either preventive administration of enalapril and carvedilol, or matching placebo. During 6-month follow-up, a significantly lower reduction of LVEF was noted in the arm taking ACEI and beta-blocker than placebo (a statistically significant difference of 3.1% in echocardiography and a difference of 3.4% on the verge of significance in magnetic resonance imaging), with a lower risk of combined clinical endpoint demonstrated in the intervention arm [30]. Thus, it appears that by recommending to consider a simultaneous introduction of preventive ACE-I/ARB and beta-blockers in patients with high or very high risk of CTR-CVT, the ESC guidelines on cardio-oncology, at least partially follow the newly introduced strategy of an early introduction of all four major “game-changing” drugs for treatment of chronic HF advocated in the ESC guidelines on HF. Nonetheless, at present, the evidence supporting preventive co-administration of ACE-I/ARB+beta-blocker is rather scarce.

**Statins**

Statins are cholesterol-lowering drugs that in patients with high- or very-high cardiovascular risk have been shown to reduce the risk of myocardial infarction, stroke, and mortality [31]. Research has shown that patients with breast cancer treated with statins might have a lower risk of cardiovascular events compared to those who do not receive this treatment. Moreover, some retrospective data report that a chronic treatment with statins might even increase the LVEF [32]. The postulated molecular mechanisms included pleiotropic effects of statins, including their anti-inflammatory, pro-apoptotic and even anti-proliferative effect on the tumor cells [33, 34]. Moreover, as cholesterol is a biochemical precursor molecule for estrogens, the modifications to the lipid metabolism equilibrium caused by statins might in result indirectly modulate the response to estrogens on the cellular levels [35].

However, data on the efficacy of statins in prevention of CTR-CVT are based mostly on retrospective, observational studies. A recently published PREVENT trial, which included patients with an early breast cancer or lymphoma, did not confirm the cardioprotective effect of statins, as
the mean (±SD) LVEF values were 61.7 ± 5.5% before treatment and 57.4 ± 6.8% at 24 months in the placebo group and 62.6 ± 6.4% before treatment and 57.7 ± 5.6% at 24 months in patients treated with 40 mg of one of the most potent statins – atorvastatin [36]. Moreover, no difference in the percentages of patients with a major (defined as by ≥10%) reduction of LVEF, or changes in LV strain, LV mass, cognitive function, or levels of inflammation biomarkers were noted between patients treated with atorvastatin and placebo. The results of the Statins to Prevent the Cardiotoxicity From Anthracyclines (STOP-CA) and Statins for the Primary Prevention of Heart Failure in Patients Receiving Anthracyclines Pilot Study (SPARE-HF) are eagerly awaited to either confirm, or repudiate the cardioprotective effect of statins in patients with cancer [37, 38].

**Spironolactone, flozins, ARNI**

The ESC guidelines on cardio-oncology do not specifically address the subject of introduction of preventive treatment with other groups which are at present considered the golden standard in patients with chronic HF. It should be noted that all of them might potentially be beneficial in preventing CTR-CVT in patients with breast cancer, who begin the oncological treatment. Spironolactone, the mineralocorticoid receptor antagonist (MRA), has been proved to reduce the morbidity and mortality in patients with HF [39–41]. Its major mechanism of action lies in the inhibition of aldosterone receptors. In patients with HF, when the activity of the RAA axis is pathologically increased, and so is the concentration of aldosterone, the end-product of this axis, the hyperactivity of aldosterone increases the myocardial fibrosis developing in response to myocardial injury. Thus, there might be a pathophysiological rationale for preventive treatment with MRA in patients treated with potentially cardio-toxic drugs.

However, the evidence supporting MRA in such setting is rather scarce, as to date there has only been one randomized trial, which included only 83 patients with breast cancer, who were treated with either doxorubicin or epirubicin. Those were randomized to preventive therapy with 25 mg daily of spironolactone or placebo. After completion of follow-up of approximately 24 weeks, preventive therapy with spironolactone resulted in a lower deterioration of LVEF assessed echocardiographically (LVEF decrease from 67.0 ± 6.1 to 65.7 ± 7.4 in the spironolactone group, and from 67.7 ± 6.3 to 53.6 ± 6.8 in the control group (between-group p < 0.001) [42]. Moreover, similarly to the findings from the studies with beta-adrenolytic drugs, the trial showed that spironolactone resulted in an attenuated increase in cardiac troponin I elevation, and while in the control group, levels of all serum biomarkers were altered by chemotherapy, no significant difference in any of the measured parameters (including NT-proBNP, troponin, creatinine kinase –
myocardial) was observed in patients taking spironolactone. Finally, the authors point a remark that the left ventricular diastolic function was maintained in patients from the spironolactone group, while a progression of diastolic dysfunction was observed in the group administered with a placebo, which further confirms that the mechanism of action of spironolactone might lay in a reduced fibrosis caused by the excessive aldosterone levels.

The results of the CECCY, PRADA, SAFE, and aforementioned spironolactone trial clearly indicate the possible benefit of RAA axis inhibitors on cardiac contractile function. Moreover, in the preclinical studies it has been demonstrated that apart from the RAA axis, an increased activation of natriuretic peptide cellular pathways decreases the risk of anthracycline-induced cardiomyopathy. Another rather novel drug in the treatment of HF is sacubitril-valsartan. Its mechanism of action lays on the inhibition of RAA axis, owing to the activity of valsartan – an ARB- and activation of natriuretic peptide pathway mediated by sacubitril – an inhibitor of nephrilisin, an enzyme responsible for degradation of many important molecules, including natriuretic peptides. Thus, the use of cardioprotective strategy with sacubitril-valsartan in patients treated with potentially cardiotoxic drugs has a strong pathophysiological rationale.

The data on the administration of sacubitril/valsartan in patients with cardiac damage caused by cancer therapy come mostly from retrospective analyses. A Spanish registry investigated 67 patients (of whom 45% were patients with breast cancer) with symptomatic HF caused by cancer therapy, in whom sacubitril/valsartan was introduced. In those subjects, significant increases in LVEF and reductions in NT-proBNP levels, and left ventricular dimensions were noted, which was followed by clinically meaningful improvement in patients' HF symptoms [43]. In another single-center analysis, echocardiographically determined cardiotoxicity developed in 28 of 635 patients, most of whom were treated with anthracyclines, and approximately a quarter with anti-HER2 therapy. Treatment with sacubitril/valsartan reduced NT-proBNP and increased patients’ exertional capacity and left ventricular ejection fraction (32.3 ± 5.5% vs. 26.7 ± 5.4%; p < 0.001) [44].

At present, there are data from only one randomized trial investigating the use of sacubitril-valsartan in patients with cancer. The study has been performed in Russia and was restricted to 112 subjects with cancer and a preexisting HF, who were administered a preventive treatment with nebivolol and eplerenone, and randomized to either sacubitril-valsartan or candesartan. After 6 months, there was a benefit of smaller LVEF reduction and improvement of quality of life with the former [45].
It should be noted that a multi-centre, double-blinded trial evaluating the efficacy and safety of sacubitril/valsartan in the prevention of CTR-CVT in patients with cancer will shortly be starting recruitment [46]. The study, which will be performed in three tertiary oncological centres in Poland will randomize a total of 480 patients with early breast cancer undergoing treatment with anthracyclines and/or anti-HER2 drugs to the highest-tolerated dose of sacubitril/valsartan or placebo in 1:1 ratio. The patients will be monitored, including a routine transthoracic echocardiography (TTE), for 24 months, and the primary endpoint of the trial will be the occurrence of a decrease in LVEF by ≥5% in TTE within 24 months. The first results are expected at the beginning of 2028, pending recruitment of participants.

Finally, the last group of drugs recommended in HF are SGLT-2 inhibitors. In the last years, several clinical trials have demonstrated their beneficial effects on heart failure outcomes, with a reduction in the risk of cardiovascular death and hospitalization for heart failure, regardless of the presence of diabetes [47, 48]. The mechanism of action of SGLT-2 inhibitors, which involves blocking glucose reabsorption in the SGLT-2 sodium-glucose co-transporters in kidneys, also leads to other effects that are beneficial in HF. By reducing sodium and water reuptake in the kidneys, SGLT-2 inhibitors increase diuresis and thus decrease blood volume, which can improve cardiac contractility. Additionally, SGLT-2 inhibitors have been shown to improve endothelial function, reduce oxidative stress, and improve myocardial cellular metabolic pathways [49]. To date, no randomized study investigated the efficacy of SGLT-2 inhibitors in prevention of CTR-CVT, and the sole evidence for their potential benefit is derived from a recent retrospective analysis, which included diabetic patients with cancer treated with SGLT-2 inhibitors, who were compared in a 1:3 ratio to control subjects not being administered SGLT-2 inhibitors. When compared to control group, patients pretreated with SGLT-2 inhibitors were at a significantly reduced risk of a composite endpoint of cardiac events, including the incidence of HF, admissions due to HF, development of new cardiomyopathy, or clinically significant arrhythmias (3% vs. 20%; p = 0.025) [50]. Moreover, the risk of all-cause death was significantly lower (9% vs. 43%; p < 0.001), albeit such strong effect on mortality is hardly attributable solely to the action of SGLT-2 inhibitors. Nonetheless, a randomized trial evaluating the efficacy of one of SGLT-2 inhibitors, empagliflozin (Empagliflozin in the Prevention of Cardiotoxicity in Cancer Patients Undergoing Chemotherapy Based on Anthracyclines – EMPACT) will soon start recruitment in Polish centres, and first results are expected in 2028 [51].

Non-pharmacological preventive measures
In addition to medication, lifestyle modifications such as exercise, a healthy diet, and smoking cessation are essential for reducing cardiovascular disease risk in breast cancer patients. Prior studies have shown that due to various factors, patients after diagnosis of cancer tend to reduce physical activity and gain weight by an average of 2.7 kg [52, 53]. Physical activity has been shown to reduce the intracellular oxidative stress, and improve exertional capacity in patients with breast cancer, what might suggest a rationale for improvement in prognosis and reduction of the risk of development of CTR-CVT [54, 55]. However, to date no clear guidelines defining the optimal exertion thresholds for groups at risk of cardiotoxicity were presented. Nonetheless, the guidelines of the American College of Sports Medicine specify the optimal physical exercise type and intensiveness in cancer survivors [56].

**Endocrine treatment and its clinical implications**

Approximately 65–70% of patients with breast cancer might have a hormone receptor-positive tumor, and in some of those patients therapy with either selective estrogen receptor modulators (SERM) or aromatase inhibitors (AI) might be initiated [57]. Although treatment with SERM or AI does not lead to development of CTRCD in a degree similar to the one observed in anthracyclines or anti-HER2 treatment, therapy with those two groups of drugs confers an increased risk of dyslipidemia, metabolic syndrome, hypertension, and thus major cardiovascular events such as myocardial infarction [58–60]. Moreover, tamoxifen has consistently been demonstrated to increase the risk of venous thromboembolism (VTE) and therefore therapy based on tamoxifen should not be recommended for patients with an increased risk of thrombotic events [61]. The ESC guidelines on cardio-oncology specify that prior to introduction of the endocrine therapies in patients with breast cancer, a 10-year risk of fatal and non-fatal cardiovascular events should be assessed, and in those perceived as of high risk, such risk should be re-evaluated every year. The detailed recommendations on baseline risk assessment and monitoring during endocrine therapy for breast cancer are listed in table V. The risk scores recommended in the guidelines are either SCORE2 or SCORE2-OP, however other validated risk scores can also be accepted [62, 63]. After risk assessment, it's of importance to discuss the risks of VTE, and major vascular events with patients at risk, while recognizing that the benefits of breast cancer treatment usually outweigh the cardiovascular risks. However, an emphasis should be placed on an optimal control of CV risk factors, including optimal lipid-lowering therapy, control of blood pressure, with an encouragement of exercise and healthy diet.

Table III. Parameters requiring verification at baseline in order to define CV risk prior to cancer treatment initiation according to the 2022 ESC guidelines on cardio-oncology [7]

| Parameters requiring verification at baseline in order to define CV risk prior to cancer treatment initiation |
|--------------------------------------------------|--------------------------------------------------|
| CV risk factors (with emphasis on the modifiable risk factors) | baseline ECG (including QTc analysis) |
| CVD history | transthoracic echocardiography (including GLS, and 3D echocardiography if possible) |
| cancer history | laboratory parameters: BNP/NT-proBNP; cTn; FPG/HbA1c; creatinine/eGFR; lipid profile |
| cancer treatment history | |
| physical examination (including vital parameters) | |

BNP – brain natriuretic peptide; cTn – cardiac troponin; CV – cardiovascular; CVD – cardiovascular disease; ECG – electrocardiography; eGFR – estimated glomerular filtration rate; FPG – fasting plasma glucose; GLS – global longitudinal strain; HbA1c – glycated haemoglobin; NT-proBNP – N-terminal pro-B-type natriuretic peptide; QTc – corrected QT interval

Table IV. Recommendations on the appropriate primary prevention of cancer therapy-related cardiovascular toxicity according to the 2022 ESC guidelines on cardio-oncology [7]

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>management of CVRF according to the 2021 ESC guidelines on CVD prevention in clinical practice is recommended before, during, and after cancer therapy</td>
<td>I, C</td>
</tr>
<tr>
<td>dextrazoxane should be considered in adult patients with cancer at high and very high CV toxicity risk when anthracycline chemotherapy is indicated</td>
<td>IIa, B</td>
</tr>
<tr>
<td>liposomal anthracyclines should be considered in adult patients with cancer at high and very high CV toxicity risk when anthracycline chemotherapy is indicated</td>
<td>IIa, B</td>
</tr>
<tr>
<td>ACE-I or ARB and beta-blockers recommended for HF should be</td>
<td>IIa, B</td>
</tr>

</table>
considered for primary prevention in high- and very high-risk patients receiving anthracyclines and/or anti-HER2 therapies

| ACE-I or ARB and beta-blockers recommended for HF should be considered for primary prevention in high- and very high-risk patients receiving targeted cancer therapies that may cause HF | IIa, C |
| statins should be considered for primary prevention in adult patients with cancer at high and very high CV toxicity risk | IIa, B |

ACE-I – angiotensin-converting enzyme inhibitors; ARB – angiotensin receptor blockers; CV – cardiovascular; CVD – CV disease; CVRF – CV risk factors; ESC – European Society of Cardiology; HER2 – human epidermal receptor 2; HF – heart failure; HFA – Heart Failure Association; ICOS – International Cardio-Oncology Society; MEK – mitogen-activated extracellular signal-regulated kinase; PI – proteasome inhibitors; RAF – rapidly accelerated fibrosarcoma; VEGFi – vascular endothelial growth factor inhibitors

**Table V.** Recommendations for baseline risk assessment and monitoring during endocrine therapy for patients with breast cancer, according to the 2022 ESC guidelines on cardio-oncology [7]

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Recommendation Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>baseline CV risk assessment and estimation of 10-year fatal and non-fatal CVD risk with SCORE2 or SCORE2-OP is recommended in BC patients receiving endocrine therapies without pre-existing CVD</td>
<td>I, C</td>
</tr>
<tr>
<td>dexrazoxane should be considered in adult patients with cancer at high and very high CV toxicity risk when anthracycline chemotherapy is indicated</td>
<td>IIa, B</td>
</tr>
<tr>
<td>liposomal anthracyclines should be considered in adult patients with cancer at high and very high CV toxicity risk when anthracycline chemotherapy is indicated</td>
<td>IIa, B</td>
