ABSTRACT

Despite the advances in techniques and technologies, the management of cavernous sinus (CS) meningiomas still remains a challenge for both neurosurgeons and radiation oncologists.

On the other hand, the improvement of the anatomical knowledge and the microsurgical techniques together with diffusion of radiosurgery are currently changing the treatment strategy, opening new perspectives to the patients which are suffering from such lesions.

The authors reviewed here the literature data. A multidisciplinary treatment algorithm is also proposed.

1. Introduction and historical remarks

The cavernous sinus (CS) region, due to its complex anatomy and its particular position in the antero-lateral skull base, has always been a challenge for neurosurgeons. The treatment of malignant diseases has presented over the past few decades a number of developments, particularly with the progress of the techniques of radiotherapy and radiosurgery. Even today however, it is still a controversial and debatable subject, and the best multimodal treatment is yet to be defined.

In 1965 Parkinson¹ was the first to realize an anatomical study and to propose a surgical approach to the CS. Despite the development of the microsurgical technique in the seventies, it was thought that microneurosurgery was reaching its furthest limits in the approach of lesions in and around the CS. The extremely high risk of damaging nervous structures, as well as causing uncontrollable haemorrhage or postoperative CSF leak seemed to be an unavoidable and insuperable obstacle. Thanks to the anatomical work of Dolenc and his surgical experiences, a rational surgical approach was eventually developed and the different relations between the lesion and the neurovascular structures were defined. In Dolenc's book preface, Yasargyl states that "there is no doubt that this type of microsurgical anatomical study is a new step in the 100 year history of neurosurgery".²

Once this frontier was opened the experiences of other groups of skull base surgeons were added and we started to develop different approaches and new techniques to address these tumours.^{3,4} More recently, new and less invasive endoscopic routes started to flourish. These approaches are less invasive and allow to address the tumour combining two complementary corridors, one antero-lateral and one trans-sphenoidal.

Still, a complete radical removal or the attempt of near total excision with anatomic-functional preservation is a very arduous exercise or even an illusion. The intimacy between tumour, nerves and vessels can be hardly overcome and represents the main unfavourable prognostic factor.

The role of both radiotherapy and radiosurgery to treat the recurrent tumours of the skull base is well known.⁵

However, it was with the gradual evolution of stereotactic radiosurgery that the method of dealing with the CS pathology has really changed. A multimodal treatment strategy combining surgery with radiotherapy, as well as radiotherapy alone in selected cases, have become the main practice to handle these tumours.

2. Anatomy

Cavernous sinus is constituted of paired venous structures located in the middle cranial fossa.^{2,6}

These structures are surrounded by dural layers, which contain neurovascular structures, and face the sella turcica, the pituitary gland, the sphenoid bone on the medial side and the temporal lobe on the lateral side.

A cavernous sinus is roughly arranged in four walls, the lateral, medial, anterior and posterior walls, and a roof.

The lateral wall faces the temporal lobe. The medial wall is mainly arranged by the sella turcica and the pituitary gland together with the sphenoid bone. The posterior margin is limited by the posterior cranial fossa. Anteriorly the cavernous sinus reaches the superior optic fissure and the near inferior surface of the anterior clinoid process. The roof faces the basal cisterns, extending anteriorly from the anterior clinoid process to the posterior clinoid process posteriorly.

The dura completely surrounds the cavernous sinus. From the floor of the medial cranial fossa the dura curves rostrally along the lateral edge of the sella and then it turns laterally to shape the lateral wall of the cavernous sinus.

The lateral dural wall of the cavernous sinus is composed of two layers, the outer dural layer (dura propria) and the inner membranous layer. The inner layer of the lateral edge of the cavernous sinus contains the critical structures, it separates the lateral wall and its contents from the venous spaces. The outer layer faces the mesial temporal lobe.

The lateral wall meningiomas usually grow between the inner and the outer layer. In this sense these lesions are substantially extra cavernous tumours. This particular condition has to be considered in surgical planning and an accurate dissection of these layers has to be performed in order to obtain a total removal of these tumours.

The cavernous sinus contains vascular and nervous structures.

The vascular structures include the cavernous segment of the internal carotid artery (ICA) and multiple venous tributaries (superior and inferior petrosal sinuses, the basilar sinus, the intercavernous sinus) as well as various draining veins of the skull base, sylvian fissure, and middle cerebral vein.

The nervous structures include the sympathetic plexus, the oculomotor nerves (III, IV, VI) and the first and second branch of the trigeminal nerve (V1, V2). According to a cranio-caudal direction, the cranial nerves III and IV as like as V1 and V2 travel inside the lateral wall of the cavernous sinus. The cranial nerve VI occupies a more medial position, behind and lateral the ICA.

According to their anatomy it is possible to identify meningiomas which arise from cavernous sinus dura itself (the strictly speaking cavernous sinus meningiomas) and meningiomas arising from the dura of the sphenoid ridge, clinoid processes and petroclival region extending to or infiltrating the cavernous sinus.

3. General considerations

In CS tumours management histological type, biological behaviour, location, extent of dural attachment and particularly relationship and encasement of neurovascular structures have to be considered. Biological behaviour can be schematically categorized into three groups: benign, intermediate malignancy and high malignancy. This subdivision is probably too simplistic, but it may facilitate decision making and the most appropriate treatment strategy. Among the most common benign oncotypes, we find meningiomas, pituitary adenomas and schwannomas. These tumours may invade and encase nearby structures. Tumours of intermediate malignancy include chordomas, chondrosarcomas, adenoid cystic carcinomas and low grade esthesioneuroblastomas. Highly malignant tumours include cranial base carcinomas, sarcomas, high grade esthesioneuroblastomas and lymphomas.⁷

Meningiomas represent 41% of all CS tumours. They can either start in areas outside the CS and subsequently invade it, or start into CS and then spread to the surrounding structures. The CS is frequently invaded by tumours (meningiomas) of the orbital apex, sella, medial sphenoid wing, middle fossa, Meckel's cave, petrous apex and tentorium. This behaviour is mostly to be found in en plaque meningiomas. On the other hand, meningiomas arising within the CS can extend and involve the same above mentioned areas, infiltrating extra or subdural spaces and bone.

Sekhar in order to assess the surgical technical difficulties and risks, and to compare different patients' series, created a classification based on the CS areas involved by the tumour, on its volume and on carotid artery involvement.^{3,8} According to this point, the most important variable influencing risks and patients outcome in the management of such lesions is the grade of involvement-encasement of nerves and vessels.

The natural history of meningiomas is still partially unknown. Although the growth rate is estimated to be between 2 and 24 mm per year, some authors found that about 23% of the meningiomas (particularly the calcified ones) did not grow.⁹

4. Surgical management

The modern approach to CS meningiomas arises in particular from the anatomical studies and surgical experiences of Dolenc.¹⁰

According to his experience the drilling of the temporal floor up to the carotid canal, together with the partial removal of the orbital roof with opening of optic canal and with the clinoidectomy provide an optimal approach to the sellar and cavernous region, almost without brain retraction. In addition, clinoidectomy and unroofing of optic canal allow a good and early control of the carotid artery and of the optic nerve.

Variations to this approach have been proposed and mainly consist in removing the orbito-zygomatic arch and extending in different directions the skull base drilling.^{3,4,11–15}

In 1997 Dolenc¹⁶ published a very large surgical series of 1050 patients operated because of tumours or vascular lesions of the CS. He described very encouraging results: 7 patients died, 9 lost vision in ipsilateral eye, 25 had a visual deterioration, 15 transient emiparesis (3 persistent), 6 needed a reoperation for CSF leak, 820 had a partial transient oculomotor paresis. Overall 770 patients regained the preoperative clinical function.

This study represented a milestone in the CS surgery. Mainly basing on this positive experience new and amazing improvements in the microsurgical technique have been made. Unfortunately the results in terms of complete tumour removal, post-operative cranial nerves deficit and patient quality of life not always corresponded to the expectations. In addition, the rate of recurrences was not negligible.

Mainly basing on the critical review of the results, the combined surgical, radiosurgical approach is nowadays widely accepted. Indeed, by combining less aggressive surgical approach with adjuvant radiosurgery, this strategy may limit the patients risk while maintaining the tumour control.^{17–19}

This new philosophy opened the way to endoscopic approaches: through a transnasal route it is possible to safely perform a partial debulking, to decompress the optic canal or to do a biopsy in cases where no clear diagnosis can be established.^{20–24}

Furthermore, in case of small asymptomatic meningiomas, considering the very slow (or even absent) growth rate of these tumours, a “wait and scan” approach appears to be a safe and more than reasonable strategy.²⁵

Despite the real benefit of an aggressive intracavernous surgery is actually debated, some selected circumstances may still require more aggressive approach. This is the case of there are some rare eveniences (mainly recurrences resistant to all treatment attempts) in which a very aggressive surgery of complete CS resection with carotid revascularization can be seen as a “salvage therapy”.²⁶

5. Radiotherapy

The intrinsic limit of microsurgery in the treatment of CS meningiomas was overcome with the advent of radiosurgery in Leksell era. The use of gammaknife and, in the most recent period, of dedicated linac and Cyberknife systems gave the

possibility to obtain excellent results in terms of local control and reduction of possible injuries. From a radiobiological point of view meningiomas are classically considered as late responding tissue and can be better controlled with a higher dose/fraction rather than conventional fractionation. Radiation injury to the cranial nerves is probably secondary to damage of small vessels and protective Schwann cells.²⁷

Major radiosurgery (RS) series report progression-free survival rates at 5 and 10 years of 80–100% and 73–98% respectively and a radiographic response in a rate of 29–69% (Table 1).^{28–46}

This technique has obtained a large consensus in the medical community of neurosurgeons but the validation of these results is limited by the paucity of randomized and controlled studies.¹⁹ The other limit is related to a technical point: the application of the RS is reserved only to lesions of small volume (range 7–15 cc). Given the proximity of CS meningiomas to radiosensitive structures, the choice of RS is usually based on a balance between the risk of delayed toxicity and delayed loss of control over the growth of the meningioma.

The peripheral dose of 12–14 Gy is accepted in most cases for CS meningiomas radiosurgery.^{28–46} The total dose is a little bit lower than the total dose in other sites' meningiomas (tentorium, falx) but it is considered safe in terms of local neurotoxicity. The proximity of the tumour to optic pathways can determine the reduction of the dose to 12 Gy in order to keep the dose to organs at risk lower than 10 Gy. In the situation of a parasellar meningioma, the distance between nerve and tumour must be carefully considered. The risk of visual impairment is related to the volume of the optic apparatus receiving high doses. A distance of 5 mm between the meningioma and the optic nerve is considered safe in single shot RS.^{39,45}

In RS technique the target volume (TV) is the contrast enhanced lesion without margin. MR and TC images are usually acquired and fusions images used to obtain a better definition in drawing both the volume that has to be irradiated and the organs at risk (OARs) to be spared. The necessity to include the dural tail in the TV is in debate among the physicians.^{47–49} It is true that the 75% of the recurrences involve the dura outside the treatment field³¹ but it is difficult to correctly define its extension and in fact the evaluation of the infiltration is totally related to the skill of the specialists involved in the contouring phase of the treatment. Importance has to be given to the verification in future trials of the importance of this issue in local control and efficacy of radiosurgery. In case that the decision to insert the dural tail in target definition is adopted, care has to be observed in dose distribution when an irregular shape of TV is dominant.

RS can be used alone or in combination with previous surgery. In the series where RS is used as first line treatment a rate of 3–15% of new or preexisting cranial nerve deficits is reported. A meta-analysis of more than 2000 CS meningiomas retrospectively evaluated and treated with either RS or surgery followed by radiotherapy or RS showed a significantly higher rate of neurological morbidity in patients undergoing surgery and RS as compared with those undergoing RS alone (59.6% vs 25.7%).⁵⁰ This fact could be explained by the negative impact of resection on micro-vascular support therefore contributing to reinforce the effects of radiosurgery and consequently,

Table 1 – Radiosurgery series.

leading to the neurological deterioration of preexisting symptoms or to the onset of new ones. In the majority of RS series a rate of 15% of new or preexisting cranial nerve deficits is reported; this element could be a support to identify RS as first line treatment in the algorithm for the management of CS meningiomas patients.^{36,51}

Another very tough challenge is the therapeutic algorithm of large meningiomas. Single fraction radiosurgery cannot be used because of the high risk of healthy tissue damage and because of a possible reduction of the local control due to the low marginal doses usually used. A complication rate of 21% was observed in patients with large CS meningiomas compared to a 3% in patients with small lesions (volume less than 10 cm³),⁴⁴ on the other hand the local control in these series is near 85% at 5 years.^{40,52}

Surgical debulking followed by RS can be an option but only in skilled neurosurgical departments.

Advanced radiotherapy techniques with standard fractionation schedules (56 Gy/28 fractions) can be a good option. At the beginning of 2000 the development of sophisticated devices (MicroMultileafCollimator, pencil beam algorithm, relocatable frame) gave the opportunity to implement better treatment plans. The result in terms of efficacy and tolerance was interesting: the reported local control reached 82–95% at 5 years and a radiological response rate of 29–31% was observed, even if this value is lower respect to the 50% noticed when RS is used.^{27,38,53–55}

With the advent of Cyberknife the use of multisession radiosurgery (mRS) in meningiomas has been evaluated.^{42,56} Dose selection was based on previous experience with radiosurgery and stereotactic radiotherapy,^{57,58} but also on previous studies concerning the dose tolerance of the cranial nerves.^{27,28,50,54} Radiobiological data indicate that a hypofractionated schedule should offer benefit in anatomical regions such as the cavernous sinus where the meningioma involves cranial nerves.⁵⁹ When a 25 Gy in 5 fractions scheme is

adopted, the total dose is theoretically comparable to the doses delivered with conventional fractionated regimens (50.4–56 Gy). In small published studies^{42,60} pre-treatment peritumoral oedema and a location adjacent to a large vein were significant risk factors for radiographic post-treatment oedema. Anyway, no major complications have been observed and improvement of pre-existing deficit is noted in 50% of the patients. Our preliminary experience in mRS is in agreement with most of the RS series. The indication for multisession radiosurgery was given by the proximity to optic nerve and chiasma or the dimension of the lesion (>3 cm). The local control rate at 5 years was of 95%. Only 3.5% of patients experienced a deterioration of preexisting symptoms (personal data). The local control is similar to RS series, the critical issues remain the short follow-up and the limited series considered.

Last but not least also proton has been advocated as advanced technique to obtain reduced complication in this specific site. In a recent study by Loma Linda University high overall 5 years local control rate (96%) was observed using 57EGy without major toxicity.⁶¹

6. Conclusions: evolution of a modern treatment

The comprehension of the CS meningiomas' natural history as well as the knowledge of the treatments results underline the need for a more modern treatment approach.

As we already stressed, a radical removal of the tumour inside the CS is often hard if not impossible and a subtotal removal is associated with a inevitably high recurrence rate.

On the other hand the therapeutic goal should be achieving tumour control while minimizing any treatment related morbidity.^{25,51}

Tentatively, in order to respect this assumption we propose the following treatment algorithm.

Small and asymptomatic intracavernous meningiomas can be observed, evolving into good candidates to radiosurgery in case of progression.

Larger meningiomas with the involvement of the lateral wall of the CS may have a safe and radical microsurgical resection.

The large extra-intracavernous meningiomas, could be managed with a combined approach. The extracavernous part can be safely removed while the remnants can be treated by RS. Multisession RS could be also take in consideration as the exclusive treatment.

The role of pre-operative radiosurgery aiming to devascularize the tumour and to allow an easier dissection from the CS walls and trigeminal branches is still under debating.⁶²

Finally, the giant sphenopetro-cavernous meningiomas represent a lesion likely beyond the possibility of a real treatment. Performing selective, partial resection in order to decompress targeted structures, carefully balancing risks and benefits, seems to be the most appropriate solution if combined with the radiosurgical treatment of the remnants.

All these considerations underline the importance of a real multidisciplinary cooperation.
